Spiral Matrix
 LeetCode · SimplifyC++ · WubCC · LeetCode · Editorial
 Array · Matrix · Simulation
 Lists: Grind 169 | CodeSignal
Problem:
 Given an m x n matrix, return all elements of the matrix in spiral order.
 Example 1:

Input: matrix = [[1,2,3],[4,5,6],[7,8,9]]
 Output: [1,2,3,6,9,8,7,4,5]
 Example 2:

Input: matrix = [[1,2,3,4],[5,6,7,8],[9,10,11,12]]
 Output: [1,2,3,4,8,11,10,9,5,6,7]
 Constraints:
 • m == matrix.length
 • n == matrix[i].length
 • 1 <= m, n <= 10
 • -100 <= matrix[i][j] <= 100

Spiral Matrix II
LeetCode · SimplifyLeet · WalkCCC · LeetCode · Editorial
Array · Matrix · Simulation
LeetCode Signal

Problem:
Given a positive integer n , generate an $n \times n$ matrix filled with elements from 1 to n^2 in spiral order.

Example 1:

1	→ 2	→ 3
8	→ 9	↓ 4
↑ 7	← 6	← 5

Input: $n = 3$
Output: $[[1,2,3],[8,9,4],[7,6,5]]$

Example 2:

Input: $n = 1$
Output: $[[1]]$

Constraints:

- $1 \leq n \leq 20$

[*] Matrix — Pattern Solution (stored optimal)

Python

```

# Function to generate spiral matrix of size n x n
def generateMatrix(n):
    # Initialize an n x n matrix with zeros
    matrix = [[0] * n for _ in range(n)]
    # Initialize the starting number to fill
    num = 1
    # Set the initial boundaries for rows and columns
    top, bottom = 0, n - 1
    left, right = 0, n - 1

    # Continue the loop until the boundaries are valid
    while top <= bottom and left <= right:
        # Traverse from left to right along the top row
        for j in range(left, right + 1):
            matrix[top][j] = num
            num += 1
        top += 1 # Move the top boundary down

        # Traverse from top to bottom along the right column
        for i in range(top, bottom + 1):
            matrix[i][right] = num
            num += 1
        right -= 1 # Move the right boundary left

        # Traverse from right to left along the bottom row if still in valid bounds
        if top <= bottom:
            for j in range(right, left - 1, -1):
                matrix[bottom][j] = num
                num += 1
            bottom -= 1 # Move the bottom boundary up

        # Traverse from bottom to top along the left column if still in valid bounds
        if left <= right:
            for i in range(bottom, top - 1, -1):
                matrix[i][left] = num
                num += 1
            left += 1 # Move the left boundary right

    return matrix

# Example usage:
print(generateMatrix(5))

```

C++

```

// Function to generate spiral matrix of size n x n
// direction vector
using namespace std;

vector<vector<int>> generateMatrix(int n) {
    // Initialize an n x n matrix filled with zeros
    vector<vector<int>> matrix(n, vector<int>(n, 0));
    int num = 1; // Start filling with 1
    int top = 0, bottom = n - 1;
    int left = 0, right = n - 1;

    // Continue until the matrix is filled the entire matrix
    while (top <= bottom && left <= right) {
        // Traverse from left to right along the top row
        for (int i = left; i <= right; i++) {
            matrix[top][i] = num++;
        }
        top++; // Move the top boundary down

        // Traverse from top to bottom along the right column
        for (int i = top; i <= bottom; i++) {
            matrix[i][right] = num++;
        }
        right--; // Move the right boundary left

        // Traverse from right to left along the bottom row if valid
        if (top <= bottom) {
            for (int i = right; i >= left; i--) {
                matrix[bottom][i] = num++;
            }
            bottom--; // Move the bottom boundary up

        // Traverse from bottom to top along the left column if valid
        if (left <= right) {
            for (int i = bottom; i >= top; i--) {
                matrix[i][left] = num++;
            }
            left++; // Move the left boundary right
        }
    }

    return matrix;
}

// Example usage:
// int n = 5;
// vector<vector<int>> result = generateMatrix(n);
// return result;
// }

```

Given a $m \times n$ grid filled with non-negative numbers, find a path from top left to bottom right, which minimizes the sum of all numbers along its path.

Note: You can only move either down or right at any point in time.

Example 1:

1	3	1
1	5	1
4	2	1

Input: grid = [[1,3,1],[1,5,1],[4,2,1]]

Output: 7

Explanation: Because the path 1 -> 3 -> 1 -> 1 -> 1 minimizes the sum.

Example 2:

Input: grid = [[1,2,3],[4,5,6]]

Output: 12

Constraints:

- $m == \text{grid.length}$
- $n == \text{grid}[0].\text{length}$
- $1 \leq m, n \leq 200$
- $0 \leq \text{grid}[i][j] \leq 200$

>> Brute Force (Matrix Interview Prep)

Python

```
# Brute Force Approach
class Solution:
    def minPathSum(self, grid: List[List[int]]) -> int:

Set Matrix Zeroes

LeetCode · SimplifyLeet · WalkCC · LeetCode · Editorial

Array · Hash Table · Matrix

Like Grid 169

Problem:

Given an $m \times n$ integer matrix `matrix`, if an element is 0, set its entire row and column to 0's.

You must do it in place.

Example 1:

Input: `matrix = [[1,2,3],[4,5,6],[7,8,9]]`
Output: `[[7,4,1],[8,5,2],[9,6,3]]`

Example 2:

Matrix · LeetCode - By Pattern

— 1620 —

LeetCode

5	1	9	11
2	4	8	10
13	3	6	7
15	14	12	16

→

15	13	2	5
14	3	4	1
12	6	8	9
16	7	10	11

Input: matrix = [[0,1,2,0],[3,4,5,2],[1,3,1,5]]

Output: [[0,0,0,0],[0,4,5,0],[0,3,1,0]]

Constraints:

- m == matrix.length
- n == matrix[0].length
- 1 <= m, n <= 200
- 231 <= matrix[i][j] <= 231 - 1

Follow up:

- A straightforward solution using O(mn) space is probably a bad idea.
- A simple improvement uses O(m + n) space, but still not the best solution.
- Could you devise a constant space solution?

Search a 2D Matrix

LeetCode · SimplifyLeetCode · WalaCC · LeetCode · Editorial

Array · Binary Search · Matrix

Utsav Grind 169

Problem:

You are given an $m \times n$ integer matrix with the following two properties:

- Each row is sorted in non-decreasing order.
- The first integer of each row is greater than the last integer of the previous row.

Given an integer target, return true if target is in matrix or false otherwise.

You must write a solution in $O(\log(m \cdot n))$ time complexity.

Example 1:

1	3	5	7
10	11	16	20
23	30	34	60

Input: matrix = [[1,3,5,7],[10,11,16,20],[23,30,34,60]], target = 3
Output: true

Example 2:

5	1	9	11
2	4	8	10
13	3	6	7
15	14	12	16

15	13	2	5
14	3	4	1
12	6	8	9
16	7	10	11

Input: matrix = [[1,3,5,7],[10,11,16,20],[23,30,34,60]], target = 13
Output: false

Constraints:

- $m == \text{matrix.length}$
- $n == \text{matrix}[i].\text{length}$
- $1 \leq m, n \leq 100$
- $-104 \leq \text{matrix}[i][j], \text{target} \leq 104$

Maximal Square

LeetCode · SimplyEasy · WalkCC · LeetCode · Editorial

Array · Dynamic Programming · Matrix

Lists Grid 189

Problem:

Given an $m \times n$ binary matrix filled with 0's and 1's, find the largest square containing only 1's and return its area.

Example 1:

1	0	1	0	0
1	0	1	1	1
1	1	1	1	1
1	0	0	1	0

```
Input: matrix =
[[1,0,1,0,0],
 [1,0,1,1,1],
 [1,1,1,1,1],
 [1,0,0,1,0]]
Output: 4
```

Example 2:

Matrix · LeetCode · By Pattern

— 1647 —

LeetCode

0	1
1	0

```
Input: matrix = [[0,1],[1,0]]
Output: 1
```

Example 3:

```
Input: matrix = [[0]]
Output: 0
```

Constraints:

- m == matrix.length
- n == matrix[0].length
- $1 \leq m, n \leq 300$
- matrix[i][j] is '0' or '1'.

Sparse Matrix Multiplication

LeetCode · Solutions · MultiC · LeetCode · Editorial

Array · Hash Table · Matrix

LeetCode Premium 98

Problem:

Given two sparse matrices mat1 of size m x k and mat2 of size k x n, return the result of mat1 x mat2. You may assume that multiplication is always possible.

Example 1:

$$\begin{bmatrix} 1 & 0 & 0 \\ -1 & 0 & 3 \end{bmatrix} \times \begin{bmatrix} 7 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix} = \begin{bmatrix} 7 & 0 & 0 \\ -7 & 0 & 3 \end{bmatrix}$$

Input: mat1 = [[1,0,0],[-1,0,3]], mat2 = [[7,0,0],[0,0,0],[0,0,1]]
Output: [[7,0,0],[-7,0,3]]

Example 2:

Input: mat1 = [[0]], mat2 = [[0]]
Output: [[0]]

Constraints:

- m == mat1.length
- k == mat1[0].length == mat2.length
- n == mat2[0].length
- 1 <= m, n, k <= 100
- 100 <= mat1[i][j], mat2[i][j] <= 100

Array · Hash Table · Matrix

Like Premium 98

Problem:
Given an m x n picture consisting of black 'B' and white 'W' pixels, return the number of lonely black pixels.

A black lonely pixel is a character 'B' that located at a specific position where the same row and same column don't have any other black pixels.

Example 1:

W	W	B
W	B	W
B	W	W

Input: picture = [[“W”,“W”,“B”],[“W”,“B”,“W”],[“B”,“W”,“W”]]
Output: 3
Explanation: All the three 'B's are black lonely pixels.

Example 2:

B	B	B
B	B	W
B	B	B

Input: picture = [[“B”,“B”,“B”],[“B”,“B”,“W”],[“B”,“B”,“B”]]
Output: 0
Constraints:

```
• m == picture.length
• n == picture[0].length
• 1 <= m, n <= 500
• picture[i][j] is 'W' or 'B'.

Problem:

You are given two images, `img1` and `img2`, represented as binary, square matrices of size `n x n`. A binary matrix has only 0s and 1s as values. We translate one image however we choose by sliding all the 1 bits left, right, up, and/or down any number of units. We then place it on top of the other image. We can then calculate the overlap by counting the number of positions that have a 1 in both images.

Note also that a translation does not include any kind of rotation. Any 1 bits that are translated outside of the matrix borders are erased.

Return the largest possible overlap.

Example 1:

1	1	0
0	1	0
0	1	0

img1

0	0	0
0	1	1
0	0	1

img2

Input: `img1 = [[1,1,0],[0,1,0],[0,0,0]]`, `img2 = [[0,0,0],[0,1,1],[0,0,1]]`
Output: 3
Explanation: We translate `img1` to right by 1 unit and down by 1 unit.

The number of positions that have a 1 in both images is 3 (shown in red).

Example 2:

Input: `img1 = [[1]], img2 = [[1]]`

Output: 1

Example 3:

Input: `img1 = [[0]], img2 = [[0]]`

Output: 0

Constraints:

- `n == img1.length == img1[0].length`
- `n == img2.length == img2[0].length`
- `1 <= n <= 30`

- `img1[i][j]` is either 0 or 1.
- `img2[i][j]` is either 0 or 1.

Find Smallest Common Element in All Rows

LeetCode · SimplyList · WalkCC · LeetCode · Editorial

Array · Hash Table · Binary Search · Matrix · Counting

Like · Premium 98

Problem:

Given an $n \times n$ matrix `mat` where every row is sorted in strictly increasing order, return the smallest common element in all rows.

If there is no common element, return `-1`.

Example 1:

Input: `mat = [[1,2,3,4,5],[2,4,5,6,10],[3,5,7,9,11],[1,3,5,7,9]]`

Output: 5

Example 2:

Input: `mat = [[1,2,3],[2,3,4],[2,3,5]]`

Output: 2

Constraints:

- $n == \text{mat.length}$
- $n == \text{mat}[i].\text{length}$
- $1 \leq m, n \leq 500$
- $1 \leq \text{mat}[i][j] \leq 104$
- `mat[i]` is sorted in strictly increasing order.

LeetCode

Lists Denny Zhang

Problem:

Given a matrix and a target, return the number of non-empty submatrices that sum to target.

A submatrix $x1, y1, x2, y2$ is the set of all cells $matrix[x][y]$ with $x1 \leq x \leq x2$ and $y1 \leq y \leq y2$.

Two submatrices $(x1, y1, x2, y2)$ and $(x1', y1', x2', y2')$ are different if they have some coordinate that is different for example, if $x1 \neq x1'$.

Example 1:

0	1	0
1	1	1
0	1	0

Input: matrix = [[0,1,0],[1,1,1],[0,1,0]], target = 0

Output: 4

Explanation: The four 1x1 submatrices that only contain 0.

Example 2:

Input: matrix = [[1,-1],[-1,1]], target = 0

Output: 5

Explanation: The two 1x2 submatrices, plus the two 2x1 submatrices, plus the 2x2 submatrix.

Example 3:

Input: matrix = [[904]], target = 0

Output: 0

Constraints:

- $1 \leq \text{matrix.length} \leq 100$
- $1 \leq \text{matrix}[0].\text{length} \leq 100$
- $-1000 \leq \text{matrix}[i][j] \leq 1000$
- $-10^4 \leq \text{target} \leq 10^4$

                col_sums[col] += matrix[bottom][col]

            # Use a dictionary to count cumulative sums in the 1D array (col_sums)
            sum_count = {0: 1}
            curr_sum = 0
            # Iterate over each column in col_sums to find the number of subarrays with sum equal to target
            for value in col_sums:
                curr_sum += value
```

```
for (let sum = 0; sum < colSum) {
    currSum += sum;
    if (sumCount[currSum - target]) {
        result += sumCount[currSum - target];
    }
    sumCount[currSum]++;
}
}
return result;
}
};

// Example usage:
// let mat = [
//   [0, 1, 0],
//   [1, 1, 1],
//   [0, 1, 0]
// ];
// let res = numSubmatrixSumTarget(mat, 0); // Expected Output: 4
// console.log(res);
```

Solution

The problem is solved by iterating through the matrix starting from the element at position (1, 1). For every element at matrix[i][j], compare it with the element at matrix[i-1][j-1]. If any two elements in this pair do not match, the matrix is not Toeplitz. This check ensures that every diagonal from the top-left to bottom-right has identical elements. In terms of auxiliary space, only constant extra space is used, which makes this approach efficient both in time and space.

#867 Transpose Matrix [Easy]

Key Insights

- The value at position (i, j) in the original matrix moves to (j, i) in the transposed matrix.
- The transposed matrix dimensions are the reverse of the original: if the original is m x n, then the transposed is n x m.
- A simple double loop is sufficient to swap the indices, ensuring O(m*n) time complexity.
- This problem handles both square and rectangular matrices.

Space & Time

Time Complexity: O(m * n)

Space Complexity: O(m * n)

n) for the new matrix holding the transposed values

Solution

The solution involves iterating over each element of the original matrix and assigning it to the corresponding position in the new matrix where the indices are swapped. We create the transposed matrix with dimensions based on the number of columns and rows of the original matrix, respectively. The approach leverages basic array manipulation with nested loops to fill in the new matrix.

#2373 Largest Local Values in a Matrix [Easy]

Key Insights

- The size of the output matrix is (n - 2) x (n - 2).
- For each valid index (i, j) in the output, examine the 3 x 3 block in grid starting at grid[i][j] to grid[i+2][j+2].
- Since each 3 x 3 block contains exactly 9 elements, finding the maximum in a block takes constant time.
- Use nested loops to slide over the grid and efficiently compute each local maximum.

Space & Time

Time Complexity: O(n^2) - We iterate over (n-2) x (n-2) positions, and for each position, we look at 9 elements.

Space Complexity: O(n^2) - The additional space is required for the output matrix.

Solution

The solution involves iterating over each possible 3 x 3 submatrix in grid. For each (i, j) starting index of the submatrix:

- Examine the nine elements from grid[i][j] to grid[i+2][j+2]. Compute the maximum value from these elements.
- Store the maximum in the corresponding position of the result matrix. Data structures used include the result matrix for storing the maximum values. The algorithmic approach involves two nested loops (one for rows and one for columns) to traverse each possible starting position of a 3 x 3 window. The simplicity of the solution comes from the fixed 3x3 block size, which enables constant-time maximum computation for each block.

#36 Valid Sudoku [Medium]

Key Insights

- Validate each row by checking for duplicate numbers while ignoring empty cells.
- Validate each column in the same way.
- Divide the board into nine 3x3 sub-boxes and check each for duplicate numbers.

```
if (curr_sum - target) in sum_count:
    result += sum_count[curr_sum - target]
# Update the dictionary with the current sum count
sum_count[curr_sum] = sum_count.get(curr_sum, 0) + 1

return result

# Example usage:
if __name__ == "__main__":
    matrix = [[0, 1, 0], [1, 1, 1], [0, 1, 0]]
    target = 0
    print(numSubmatrixSumTarget(matrix, target)) # Expected Output: 4

        int n = matrix[0].size();
        int result = 0;

        // Consider every possible pair of rows as boundaries for the submatrix
        for (int top = 0; top < m; ++top) {
            vector<int> colSums(n, 0); // Initialize column sums for each pair
            for (int bottom = top; bottom < m; ++bottom) {
                // Summarize column sums for the current bottom row
                for (int col = 0; col < n; ++col) {
                    colSums[col] += matrix[bottom][col];
                }

                // Use unordered_map to find the number of subarrays in colSums that sum to target
                unordered_map<int, int> sumCount;
                sumCount[0] = 1;
                int currSum = 0;
            }
        }
    }
};
```

Quick Review — Matrix 20 questions · insights · complexity · solution

#422 Valid Word Square [Easy]

Key Insights

- The k-th row should be equal to the k-th column.
- Not every word is the same length; checks must be performed within bounds.
- Iterating over each character and cross-verifying with the corresponding column character is sufficient.

Space & Time

Time Complexity: O(N * L) where N is the number of words and L is the average length of the words.

Space Complexity: O(1) additional space is used for the checking procedure.

Solution

We iterate through each word (row) and each character (column) in the word. For every character at position (i, j), we confirm that there is a corresponding word at index j and that its length is greater than i. Then we check that the character at position (j, i) in that word is the same as the current character. If any of these checks fail, we return false. If all checks pass, the words form a valid word square.

#566 Reshape the Matrix [Easy]

Key Insights

- Check if the reshape operation is possible by comparing the total elements (m * n with r * c).
- Flatten the original matrix while preserving the row-traversing order.
- Use the flattened list to build the new matrix row by row.
- If the total number of elements does not match, simply return the original matrix.

Space & Time

Time Complexity: O(m * n)

n) as we iterate through all elements of the matrix once.

Space Complexity: O(m * n)

n) for the additional list used to store flattened elements (or the new matrix).

Solution

The solution involves first checking whether the reshape is possible by ensuring that the product of the rows and columns of the original matrix equals that of the desired matrix (r * c). If not, the original matrix is returned. Otherwise, the matrix is flattened into a one-dimensional list, preserving the row-order traversal. Finally, the flattened list is segmented by the new column size c to form the reshaped matrix. The primary data structures used include a list (or array) for flattening the matrix and then another list (or vector/array) to hold the final reshaped matrix.

#766 Toeplitz Matrix [Easy]

Key Insights

- Each element (except those in the first row and first column) must be equal to its top-left neighbor.
- You can validate the matrix by iterating from the second row/column and comparing each element with matrix[i-1][j-1].
- This simple check allows you to determine if every diagonal has the same elements without extra space.
- For streaming data (loading one row at a time), maintain the previous row for comparison.

Space & Time

Time Complexity: O(m * n)

Space Complexity: O(1)

- Use hash sets (or equivalent data structures) to keep track of seen digits for rows, columns, and boxes.
- The board size is fixed (3x3), so the overall time complexity is constant with respect to input size.

Space & Time

Time Complexity: O(1) — Since the board size is fixed at 9x9.

Space Complexity: O(1) — The extra space used by the sets is bounded by the fixed board size.

Solution

The solution uses three main data structures: an array of sets for rows, an array of sets for columns, and an array of sets for 3x3 sub-boxes. For each cell, if it is not empty, check if the number is already present in the corresponding row, column, or box. If found, return false immediately. Otherwise, add the number to the respective sets. Compute the index for the 3x3 sub-box using the formula: (row_index // 3) * 3 + (col_index // 3). If no duplicates are found after traversing the entire board, the board is considered valid.

#48 Rotate Image [Medium]

Key Insights

- The rotation can be achieved in two steps: first transpose the matrix and then reverse each row.
- Transposing the matrix swaps matrix[i][j] with matrix[j][i], converting rows into columns.
- Reversing each row post-transposition yields the desired clockwise rotation.
- This approach works in-place with O(1) extra space.

Space & Time

Time Complexity: O(n^2) since every element is processed during the transpose and row reversal.

Space Complexity: O(1) as the operations are performed in-place without extra data structures.

Solution

The solution leverages a two-step in-place transformation:

- Transpose the matrix: Iterate through the matrix and swap each element (i, j) with element (j, i) for j > i.
- Reverse each row: After the transpose, each row is reversed to rotate the matrix 90 degrees clockwise. The key trick is to realize that a transpose followed by a reverse of each row achieves the rotation without needing extra space.

#54 Spiral Matrix [Medium]

Key Insights

- Use four boundaries: top, bottom, left, and right to track the current layer.
- Traverse right across the top row, then down the right column, then left on the bottom row, and finally up the left column.
- After each direction, adjust the corresponding boundary to move inward.
- Continue the traversal until the boundaries cross.

Space & Time

Time Complexity: O(m * n) since each element is visited exactly once.

Space Complexity: O(1) extra space (excluding the space required for the output list).

Solution

The solution uses a simulation approach with boundary pointers (top, bottom, left, right). At each step, the boundaries indicate the current submatrix to traverse. You iterate as follows:

- Traverse from left to right along the top boundary.
- Traverse downward along the right boundary.
- If the top boundary has not passed the bottom, traverse from right to left along the bottom boundary.
- If the left boundary has not passed the right, traverse upward along the left boundary.
- After each traversal, the boundaries are adjusted inward. This continues until all elements have been visited.

#59 Spiral Matrix II [Medium]

Key Insights

- Use four pointers (top, bottom, left, right) to keep track of the matrix boundaries.

- Traverse the matrix in a spiral: move right along the top row, then down the right column, left along the bottom row, and finally up the left column.
- Update the boundary pointers after each complete traversal of one side.
- Continue until all numbers from 1 to n^2 are filled into the matrix.

Space & Time

Time Complexity: $O(n^2)$

Space Complexity: $O(n^2)$ (required for the output matrix)

Solution

We simulate the spiral movement by initializing four pointers: top, bottom, left, and right, which denote the current boundaries of the matrix that have not yet been filled. For each iteration, we:

- Traverse from left to right along the top boundary, then increment the top pointer. - Traverse from top to bottom along the right boundary, then decrement the right pointer. - If there are rows remaining, traverse from right to left along the bottom boundary, then decrement the bottom pointer. - If there are columns remaining, traverse from bottom to top along the left boundary, then increment the left pointer. This algorithm ensures that the matrix is filled in a spiral order until all numbers are placed.

#76 Minimum Path Sum [Medium]

Key Insights

- The problem can be solved using Dynamic Programming.
- The optimal solution for each cell depends on the minimum path sum of the cell above it and the cell to its left.
- Since you can only move right or down, only two adjacent cells affect the current cell's result.
- Edge cases include the first row and first column, which have only one direction of movement.

Space & Time

Time Complexity: $O(m \times n)$, where m and n are the number of rows and columns.

Space Complexity: $O(m \times n)$ for the DP table (this can be optimized to $O(n)$ with in-place computations).

Solution

We use a Dynamic Programming (DP) approach where we create a DP table (or use the grid itself) that stores the minimum path sum to each cell. For each cell (i, j) :

- If $i = 0$ (first row), the only possible path is from the left. - If $j = 0$ (first column), the only possible path is from above. - For other cells, the minimum path sum is the cell value plus the minimum of the two possible previous cells (above and left). This ensures that by the time we reach the bottom-right cell, we have accumulated the minimum sum required to reach that cell.

#73 Set Matrix Zeroes [Medium]

Key Insights

- The challenge is to mark rows and columns that need to be zeroed without using extra space.
- A common trick is to use the first row and first column as markers.
- Special care is needed for the first row and first column, as they are also used as markers.
- The algorithm involves two passes: one for marking and one for updating the matrix based on the markers.

Space & Time

Time Complexity: $O(m \times n)$

Space Complexity: $O(1)$ (in-place, using only constant extra space)

Solution

We can solve this problem by using the first row and first column of the matrix as markers. First, determine if the first row or first column needs to be zeroed, then traverse the rest of the matrix and mark the corresponding first row and column positions if a zero is encountered. Finally, update the matrix backward using the markers, and finally update the first row and column if needed.

Matrix · LeetCode · By Pattern

— 1729 —

LeetCode

Time Complexity: $O(m \times k \times n)$ in the worst-case, but significantly lower when many elements are zero.

Space Complexity: $O(m \times n)$ for the resulting matrix.

Solution

We loop through each row of `mat1` and for every non-zero element, we traverse the corresponding row in `mat2`. By checking if an element in both matrices is non-zero before multiplying, we avoid redundant calculations. This optimization leverages the sparsity of the matrices. We use standard nested loops along with conditional checks to implement this efficient multiplication.

#488 Diagonal Traverse [Medium]

Key Insights

- Traverse the matrix diagonally with alternating directions: upward (top-right) and downward (bottom-left).
- When the traversal reaches a boundary (top, bottom, left, or right), adjust the position and change the direction.
- Use simulation to process each element exactly once while managing the indices based on the current direction.

Space & Time

Time Complexity: $O(m \times n)$ where m is the number of rows and n is the number of columns, as every element is processed once.

Space Complexity: $O(m \times n)$ for the output array (excluding the input matrix), while additional space usage remains constant.

Solution

The solution simulates the diagonal traversal using a direction flag (1 for upward and -1 for downward).

- Begin at the matrix's top-left corner. - Append the current element to the result. - Depending on the current direction: If moving upward, decrease the row and increase the column. If moving downward, increase the row and decrease the column. - Adjust for boundary hits: When moving upward: If at the last column, increment the row and switch direction. If at the first row, increment the column and switch direction. When moving downward: If at the last row, increment the column and switch direction. If at the first column, increment the row and switch direction. This process continues until all elements are added to the result array.

#531 Lonely Pixel I [Medium]

Key Insights

- Count the number of 'W' pixels in each row.
- Count the number of 'W' pixels in each column.
- A pixel is considered lonely if the count in its corresponding row and column is exactly 1.
- Two passes through the matrix can efficiently solve the problem: one for counting and one for checking conditions.

Space & Time

Time Complexity: $O(m \times n)$, where m and n are the dimensions of the picture.

Space Complexity: $O(m \times n)$, used to store the row and column counts.

Solution

The solution works by first scanning the entire matrix to compute the number of black pixels in each row and each column using two arrays/lists. Once these counts are available, a second pass through the matrix determines for each black pixel if it is lonely by checking if its corresponding row and column count equals 1. The approach uses simple array data structures for tallying counts and ensures that each element is processed only a constant number of times.

#723 Candy Crush [Medium]

Key Insights

- Use a simulation approach: repeatedly detect crushable candies and simulate their removal.
- Traverse horizontally and vertically to mark candies that are in groups of three or more.

Matrix · LeetCode · By Pattern

— 1731 —

LeetCode

Time Complexity: $O(m \times n \times \log(n))$ where m is the number of rows and n is the number of columns (binary search in each row for each candidate from the first row).

Space Complexity: $O(1)$ (only a few auxiliary variables are used).

Solution

The solution iterates over each element (candidate) in the first row of the matrix. For each candidate, it checks if the candidate is present in every other row using binary search, taking advantage of the sorted order. If a candidate is found in every row, return it immediately as it will be the smallest such common element because the first row is processed in order. If no candidate is common across all rows, return -1.

#1074 Number of Submatrices That Sum to Target [Hard]

Key Insights

- Transform the 2D submatrix sum problem into multiple 1D subarray sum problems.
- Precompute cumulative sums by fixing two row boundaries and then summing columns between these rows.
- Use a hash table (or dictionary) to count the number of subarrays with a given sum, reducing the problem to the classic "subarray sum equals k" question.
- Iterate over all possible row pairs and for each, treat the column sums as an array where the target sum is sought.

Space & Time

Time Complexity: $O(n^3 \times m)$, where n is the number of rows and m is the number of columns.

Space Complexity: $O(m)$, using the hash table for storing cumulative sums along the columns.

Solution

The idea is to iterate over all pairs of rows (top and bottom) and, for each pair, compute the cumulative column sums between these rows. This converts the problem into finding the number of subarrays in a one-dimensional array (the column sums) that add up to the target. For each such 1D problem, use a hash table to track the frequency of cumulative sums seen so far and count how many times the difference (current sum - target) has been seen. This count gives the number of subarrays ending at the current index which sum to target. Combining counts from all possible row pairs yields the final result.

Matrix · LeetCode · By Pattern

— 1733 —

LeetCode

The algorithm works in three main steps:

- Check if the first row or first column should be zeroed (store this in two variables). - Iterate through the rest of the matrix: for any element that is zero, mark its row and column by setting the corresponding element in the first row and first column to zero. - Iterate through the matrix again (excluding the first row and column) and set elements to zero if their row or column marker is zero. - Finally, zero out the first row and/or first column if needed.

This approach avoids extra space usage apart from the two boolean flags while ensuring that the matrix is updated correctly.

#74 Search a 2D Matrix [Medium]

Key Insights

- The matrix is essentially a flattened sorted array due to its properties.
- Use binary search to efficiently determine if the target exists.
- Map the 1D binary search index to the corresponding 2D matrix coordinates using division and modulus operations.
- Achieve $O(\log(m \times n))$ time complexity by navigating the matrix as if it were a single sorted list.

Space & Time

Time Complexity: $O(\log(m \times n))$

Space Complexity: $O(1)$

Solution

We can treat the matrix as a flattened sorted list without physically copying the elements. Given the total number of elements $= m \times n$, perform binary search on indices ranging from 0 to $(m \times n - 1)$. For any index `mid`, calculate its corresponding row as `mid / n` and column as `mid % n`. Compare the element at `matrix[mid / n][mid % n]` with the target. If it equals target, return true; if it is less than target, search the right half; otherwise, search the left half.

#221 Maximal Square [Medium]

Key Insights

- Use dynamic programming to build a solution where each cell in the DP table represents the side length of the largest square ending at that cell.
- If the current cell is '1', its DP value is the minimum of the top, left, and top-left neighbors plus one.
- Update a global maximum side length during the process to determine the area.
- The square's area is the square of its maximum side length.

Space & Time

Time Complexity: $O(m \times n)$, where m is the number of rows and n is the number of columns.

Space Complexity: $O(m \times n)$ for the DP table (this can be optimized to $O(n)$ with space reduction techniques).

Solution

We use a two-dimensional dynamic programming approach. We define a DP matrix with one extra row and column to simplify boundary conditions. For each cell (i, j) in the input matrix, if the value is '1', then we calculate the DP value as the minimum of its top, left, and top-left neighboring DP values plus one. This value represents the side length of the square ending at (i, j) . We also keep track of the maximum side length found and finally compute the area of the maximal square by squaring the maximum side length.

#311 Sparse Matrix Multiplication [Medium]

Key Insights

- Exploit sparsity by iterating only over non-zero elements.
- For each non-zero element in `mat1`, multiply it with corresponding non-zero elements in `mat2`.
- Accumulate the product into the result matrix.
- This approach reduces unnecessary multiplication operations when many elements are zero.

Space & Time

Matrix · LeetCode · By Pattern

— 1730 —

LeetCode

- Instead of removing candies immediately, mark them for removal and update the board once for the entire pass.
- After crushing, simulate gravity by shifting non-zero candies downward in each column.
- Continue the process until no further candy crushes can be detected.

Space & Time

Time Complexity: $O(m \times n^2)$

in the worst case since each iteration includes scanning the $m \times n$ grid and then applying gravity.

Space Complexity: $O(m \times n)$

for maintaining additional markers or flags (or using the board itself with in-place modifications).

Solution

The solution involves iteratively scanning the board to identify candy groups that should be crushed using two passes:

- Horizontal Check - For each row, check segments of 3 consecutive candies. - Vertical Check - For each column, check segments of 3 consecutive candies. If any candy qualifies, mark its position for crushing. After marking, update the board by turning all marked positions into 0. Then, for each column, drop down non-zero candies such that all empty cells (zeros) are at the top. Repeat this process until no group of 3 or more adjacent candies is found. Key data structures include the board array and a temporary marker (can be implicit by using signs or a separate boolean matrix) for tracking candies to crush. The algorithm ensures a stable board before returning it.

#835 Image Overlap [Medium]

Key Insights

- You only need to consider the positions of 1's in each matrix.
- The overlap count for a given translation can be computed by comparing the relative differences between the positions of 1's in the two images.
- Using a hash map (or dictionary) to count how many times each translation vector appears lets you compute the maximum overlap efficiently.
- The translation operation is equivalent to shifting the positions, so the best possible translation is the one that aligns the most pairs of 1's.

Space & Time

Time Complexity: $O(n^4)$ in the worst-case when using a nested iteration over positions for both matrices, though the average situation is typically better since not all cells are 1.

Space Complexity: $O(n^2 \times 2)$ for storing the positions of 1's and the counts for translation vectors.

Solution

The solution involves the following steps:

- Traverse both images to record the coordinates of all 1's. - For every pair of 1's (one from the first image, one from the second), compute the translation vector (offset) that aligns them. - Use a hash map to count how many times each offset appears. - The maximum count recorded in the hash map is the largest overlap achievable by any translation. This approach avoids simulating every possible slide over the matrix and focuses only on relative alignments of 1's.

#1190 Find Smallest Common Element in All Rows [Medium]

Key Insights

- Since every row is strictly increasing, binary search can be used efficiently to check for the presence of an element in a row.
- Iterating over the first row's elements and verifying their presence in all other rows is an effective approach.
- Early termination is possible if an element is not found in any one row.
- Time complexity is manageable given the constraints, even using binary search for each candidate across rows.

#16 Linked List — 23 questions · #16 of 21

#21

EASY

Merge Two Sorted Lists

LeetCode · SimplifyLife · WikiCNC · LeetCode · Editorial

Linked List · Recursion

Lists · Grid 169

Problem:

You are given the heads of two sorted linked lists `list1` and `list2`.

Merge the two lists into one sorted list. The list should be made by splicing together the nodes of the first two lists.

Return the head of the merged linked list.

Example 1:

Example 2:

Input: list1 = [], list2 = []

Output: []

Example 3:

Input: list1 = [], list2 = [0]

Output: [0]

Constraints:

- The number of nodes in both lists is in the range $[0, 50]$.
- $-100 \leq \text{Node.val} \leq 100$
- Both `list1` and `list2` are sorted in non-decreasing order.

Reverse Linked List

LeetCode · Simplest · RustCC · LeetCode · Editorial

Linked List · Recursion

List: Grind 169

Problem:

Given the head of a singly linked list, reverse the list, and return the reversed list.

Example 1:

Linked List · LeetCode · By Pattern

— 1753 —

LeetCode

Example 2:

Example 3:

Input: head = []
Output: []

Constraints:

- The number of nodes in the list is the range [0, 5000].
- 5000 <= Node.val <= 5000

Follow up: A linked list can be reversed either iteratively or recursively. Could you implement both?

>> Brute Force [Linked List] Interview Prep

```

Python
# Brute Force Approach
class Solution:
    def reverseList(self, head):
        # Base case: if head is None, return None
        if not head:
            return None
        # Collect values, rebuild in reverse
        vals = []
        curr = head
        while curr:
            vals.append(curr.val)
            curr = curr.next
        dummy = ListNode(0)
        curr = dummy
        for v in reversed(vals):
            curr.next = ListNode(v)
            curr = curr.next
        return dummy.next

#234 EASY
Palindrome Linked List
LeetCode · Simplified · WalkCC · LeetCode · Editorial
Linked List · Two Pointers · Recursion
Lists Grid 189

Problem:
Given the head of a singly linked list, return true if it is a palindrome or false otherwise.
Example 1:
1 -> 2 -> 2 -> 1
Input: head = [1,2,2,1]
Output: true
Example 2:
1 -> 2 -> 3 -> 2 -> 1
Input: head = [1,2,3,2,1]
Output: true
```

1 → 2

Input: head = [1,2]
Output: false

Constraints:

- The number of nodes in the list is in the range [1, 105].
- 0 ≤ Node.val ≤ 9

Follow up: Could you do it in O(n) time and O(1) space?

```
Python
# Definition for singly-linked list.

Design HashMap

LeetCode · SimplifyLeet · WalkCC · LeetCode · Editorial

Array · Hash Table · Linked List · Design · Hash Function
Like Deemy Zhang

Problem:

Design a HashMap without using any built-in hash table libraries.

Implement the MyHashMap class:

- MyHashMap() initializes the object with an empty map.
- void put(int key, int value) inserts a (key, value) pair into the HashMap. If the key already exists in the map, update the corresponding value.
- int get(int key) returns the value to which the specified key is mapped, or -1 if this map contains no mapping for the key.
- void remove(key) removes the key and its corresponding value if the map contains the mapping for the key.

Example 1:

EASY

Middle of the Linked List

LeetCode · SimplifyLeetCode · WubCC · LeetCode · Editorial

Linked List · Two Pointers

Lists - Grid 100

Problem:

Given the head of a singly linked list, return the middle node of the linked list.

If there are two middle nodes, return the second middle node.

Example 1:

Input: head = [1,2,3,4,5]

Output: [3,4,5]

Explanation: The middle node of the list is node 3.

Example 2:

Input: head = [1,2,3,4,5,6]

Output: [4,5,6]

Explanation: Since the list has two middle nodes with values 3 and 4, we return the second one.

Constraints:

- The number of nodes in the list is in the range [1, 100].
- 1 <= Node.val <= 100

EASY

Delete N Nodes After M Nodes of Linked List

LeetCode · SimplifyLeetCode · WubCC · LeetCode · Editorial

Linked List

Lists - Premium 50

Problem:

You are given the head of a linked list and two integers m and n.

Traverse the linked list and remove some nodes in the following way:

- Start with the head as the current node.
- Keep the first m nodes starting with the current node.
- Remove the next n nodes
- Keep repeating steps 2 and 3 until you reach the end of the list.

Return the head of the modified list after removing the mentioned nodes.

Example 1:

Input: head = [1,2,3,4,5,6,7,8,9,10,11,12,13], m = 2, n = 3

Output: [1,2,6,7,11,12]

Explanation: Keep the first (m = 2) nodes starting from the head of the Linked List (1 -> 2) and remove the next (n = 3) nodes.

Linked List · LeetCode - By Pattern — 1788 —

LeetCode

Delete the next ($n = 3$) nodes ($3 \rightarrow 4 \rightarrow 5$) show in red nodes.
Continue with the same procedure until reaching the tail of the Linked List.
Head of the Linked List after removing nodes is returned.

Example 2:

Input: head = [1,2,3,4,5,6,7,8,9,10,11], m = 1, n = 3
Output: [1,5,9]

Explanation: Head of Linked List after removing nodes is returned.

Constraints:

- The number of nodes in the list is in the range [1, 104].
- $1 \leq m \leq 106$
- $1 \leq n \leq 1000$

Follow up: Could you solve this problem by modifying the list in-place?

```
Python
# Definition for singly-linked list.
class ListNode:
    def __init__(self, val=0, next=None):
        self.val = val
        self.next = next

class Solution:
    def deleteNodes(self, head: ListNode, m: int, n: int) -> ListNode:
        # Initialize the current pointer at the head of the list.
        current = head
        while current:
            # Loop m nodes, traverse n-1 next pointers
            for i in range(1, m):
                if current is None: # If list ends, break
                    break
                current = current.next
            # If we have reached the end of the list, break the loop.
            if current is None:
                break
            # Start deletion from the next node after the m-th node.
            temp = current.next
            # Delete next n nodes.
            for j in range(1, n):
                if temp is None:
                    break
                temp = temp.next
            current = temp
        return head
```

Add Two Numbers

LeetCode · Simple · Rust · C++ · LeetCode · Editorial

Linked List · Math · Recursion

LeetCode 169

Problem:

You are given two non-empty linked lists representing two non-negative integers. The digits are stored in reverse order, and each of their nodes contains a single digit. Add the two numbers and return the sum as a linked list.

You may assume the two numbers do not contain any leading zero, except the number 0 itself.

Example 1:

Input: l1 = [2,4,3], l2 = [5,6,4]

Output: [7,0,8]

Explanation: 342 + 465 = 807.

Example 2:

Input: l1 = [0], l2 = [0]

Output: [0]

Example 3:

Input: l1 = [9,9,9,9,9,9], l2 = [9,9,9,9]

Output: [8,9,9,9,8,0,1]

Constraints:

- The number of nodes in each linked list is in the range [1, 100].
- $0 \leq \text{Node.val} \leq 9$
- It is guaranteed that the list represents a number that does not have leading zeros.

MEDIUM

Remove Nth Node From End of List

LeetCode · SinglyList · MEDIUM · LeetCode · Editorial

Linked List · Two Pointers

Lists Grid 169

Problem:

Given the head of a linked list, remove the nth node from the end of the list and return its head.

Example 1:

Input: head = [1,2,3,4,5], n = 2

Output: [1,2,3,5]

Example 2:

Input: head = [1], n = 1

Output: []

Example 3:

Input: head = [1,2], n = 1

Output: [1]

Constraints:

• The number of nodes in the list is sz.

• 1 <= sz <= 30

• 0 <= Node.val <= 100

• 1 <= n <= sz

Follow up: Could you do this in one pass?

LRU Cache

LeetCode · Interview · Wiki · LeetCode · Editorial

Hash Table · Linked List · Design

List · Grind 169

Problem:

Design a data structure that follows the constraints of a Least Recently Used (LRU) cache.

Implement the LRUCache class:

- LRUCache(int capacity) Initialize the LRU cache with positive size capacity.
- get(int key) Return the value of the key if the key exists, otherwise return -1.
- void put(int key, int value) Update the value of the key if the key exists. Otherwise, add the key-value pair to the cache. If the number of keys exceeds the capacity from this operation, evict

Problem:

Given the head of a linked list, return the list after sorting it in ascending order.

Example 1:

Linked List · LeetCode - By Pattern

— 1854 —

LeetCode

Input: head = [4,2,1,3]
Output: [1,2,3,4]

Example 2:

Input: head = [-1,5,3,4,0]
Output: [-1,0,3,4,5]

Example 3:

Input: head = []
Output: []

Constraints:

• The number of nodes in the list is in the range [0, 5 * 10⁴].

• -105 <= Node.val <= 105

Follow up: Can you sort the linked list in O(n log n) time and O(1) memory (i.e. constant space)?

Linked List
LeetCode 147

Problem:
Given the head of a singly linked list, group all the nodes with odd indices together followed by the nodes with even indices, and return the reordered list.
The first node is considered odd, and the second node is even, and so on.
Note that the relative order inside both the even and odd groups should remain as it was in the input.
You must solve the problem in $O(1)$ extra space complexity and $O(n)$ time complexity.

Example 1:

Input: head = [1,2,3,4,5]
Output: [1,3,5,2,4]

Example 2:

Input: head = [2,1,3,5,6,4,7]
Output: [2,3,6,7,1,5,4]

Constraints:

- The number of nodes in the linked list is in the range [0, 104].
- $-106 \leq \text{Node.val} \leq 106$

```

// Definition for singly-linked list.
// struct ListNode {
//     int val;
//     ListNode *next;
// };
//
// param [ListNode] head
// return [ListNode]
var sortList = function(head) {
    if (head === null || head.next === null) {
        return head;
    }
    let slow = head;
    let fast = head.next;
    while (fast && fast.next) {
        slow = slow.next;
        fast = fast.next.next;
    }
    let mid = slow.next;
    slow.next = null;
    let l1 = sortList(head);
    let l2 = sortList(mid);

    const dummy = new ListNode();
    let cur = dummy;
    while (l1 && l2) {
        if (l1.val <= l2.val) {

Plus One Linked List

LeetCode - LeetCode - WALTER - LeetCode - Editorial

Linked List - Math - Recursion

LeetCode Premium 98

Problem:

Given a non-negative integer represented as a linked list of digits, plus one to the integer.

The digits are stored such that the most significant digit is at the head of the list.

Example 1:

Input: head = [1,2,3]

Output: [1,2,4]

Example 2:

Input: head = [0]

Output: [1]

Constraints:

• The number of nodes in the linked list is in the range [1, 100].

• 0 <= Node.val <= 9

• The number represented by the linked list does not contain leading zeros except for the zero itself.

Flatten a Multilevel Doubly Linked List

LeetCode · Simplify Interview · Stack · LeetCode - Editorial

Linked List · DFS · Doubly Linked List

LeetCode Premium 98

Problem:

You are given a doubly linked list, which contains nodes that have a next pointer, a previous pointer, and an additional child pointer. This child pointer may or may not point to a separate doubly linked list, also containing these special nodes. These child lists may have one or more children of their own, and so on, to produce a multilevel data structure as shown in the example below.

Given the head of the first level of the list, flatten the list so that all the nodes appear in a single-level, doubly linked list. Let curr be a node with a child list. The nodes in the child list should appear after curr and before curr.next in the flattened list.

Return the head of the flattened list. The nodes in the list must have all of their child pointers set to null.

Example 1:

Input: head = [1,2,3,4,5,6,null,null,7,8,9,10,null,null,11,12]
Output: [1,2,3,7,8,11,12,9,10,4,5,6]
Explanation: The multilevel linked list in the input is shown. After flattening the multilevel linked list it becomes:

Example 2:
Input: head = [1,2,null,3]
Output: [1,3,2]
Explanation: The multilevel linked list in the input is shown. After flattening the multilevel linked list it becomes:

Example 3:
Input: head = []
Output: []
Explanation: There could be empty list in the input.

Constraints:

- The number of Nodes will not exceed 1000.

- 1 ≤ Node.val ≤ 10⁵

How the multilevel linked list is represented in test cases:

We use the multilevel linked list from Example 1 above:

```

1---2---3---4---5---6---NULL
|
7---8---9---10---NULL
|
11---12---NULL

```

The serialization of each level is as follows:

```

[1,2,3,4,5,6,null]
[7,8,9,10,null]
[11,12,null]

```

```

// Definition for a Node.
// class Node {
//     val: number
//     prev: Node | null
//     next: Node | null
//     child: Node | null
//     constructor(val?: number, prev?: Node | null, next?: Node | null, child?: Node | null) {
//         this.val = (val===undefined ? 0 : val)
//         this.prev = (prev===undefined ? null : prev)
//         this.next = (next===undefined ? null : next)
//         this.child = (child===undefined ? null : child)
//     }
// }

def flatten(head: Node | null): Node | null {
    // If head is null, simply return head.
    if not head:
        return head

    // Helper function to perform DFS and return the tail of the flattened list.
    def dfs(node: Node): Node | null {
        current = node
        last = None
        while current:
            next_node = current.next
            # Store current.next before modification.

Design Circular Queue

LeetCode · Simplilearn · WUOLCC · LeetCode · Editorial

Array · Linked List · Design · Queue

Like Denny Zhang

Linked List · LeetCode - By Pattern

— 1882 —

LeetCode

Problem:

Design your implementation of the circular queue. The circular queue is a linear data structure in which the operations are performed based on FIFO (First In First Out) principle, and the last position is connected back to the first position to make a circle. It is also called "Ring Buffer".

One of the benefits of the circular queue is that we can make use of the spaces in front of the queue. In a normal queue, once the queue becomes full, we cannot insert the next element even if there is a space in front of the queue. But using the circular queue, we can use the space to store new values.

Implement the MyCircularQueue class:

- MyCircularQueue(k) Initializes the object with the size of the queue to be k.
- int Front() Gets the front item from the queue. If the queue is empty, return -1.
- int Rear() Gets the last item from the queue. If the queue is empty, return -1.
- boolean enQueue(int value) Inserts an element into the circular queue. Return true if the operation is successful.
- boolean deQueue() Deletes an element from the circular queue. Return true if the operation is successful.
- boolean isEmpty() Checks whether the circular queue is empty or not.
- boolean isFull() Checks whether the circular queue is full or not.

You must solve the problem without using the built-in queue data structure in your programming language.

Example 1:

```

Input
["MyCircularQueue", "enQueue", "enQueue", "enQueue", "enQueue", "Rear", "isFull", "deQueue", "enQueue", "Rear"]
[[3], [1], [2], [3], [4], [1], [1], [1], [4], [1]]
Output
[null, true, true, true, false, 3, true, true, true, 4]

```

Explanation
MyCircularQueue myCircularQueue = new MyCircularQueue(3);
myCircularQueue.enQueue(1); // return True
myCircularQueue.enQueue(2); // return True
myCircularQueue.enQueue(3); // return True
myCircularQueue.enQueue(4); // return False
myCircularQueue.Rear(); // return 3
myCircularQueue.isFull(); // return True
myCircularQueue.deQueue(); // return True
myCircularQueue.enQueue(4); // return True
myCircularQueue.Rear(); // return 4

Constraints:

- 1 <= k <= 1000
- 0 <= value <= 1000
- At most 3000 calls will be made to enQueue, deQueue, Front, Rear, isEmpty, and isFull.

Design Linked List
[LeetCode](#) · [SimpleHash](#) · [WuJCC](#) · [LeetCode](#) · [Editorial](#)
 Linked List · Design
 Lists Denny Zhang

Problem:
 Design your implementation of the linked list. You can choose to use a singly or doubly linked list. A node in a singly linked list should have two attributes: val and next, val is the value of the current node, and next is a pointer/reference to the next node. If you want to use the doubly linked list, you will need one more attribute prev to indicate the previous node in the linked list. Assume all nodes in the linked list are 0-indexed.

Linked List · LeetCode · By Pattern — 1898 — LeetCode

Implement the MyLinkedList class:

- MyLinkedList() Initializes the MyLinkedList object.
- int get(int index) Get the value of the indexth node in the linked list. If the index is invalid, return -1.
- void addAtHead(int val) Add a node of value val before the first element of the linked list. After the insertion, the new node will be the first node of the linked list.
- void addAtTail(int val) Append a node of value val as the last element of the linked list.
- void addAtIndex(int index, int val) Add a node of value val before the indexth node in the linked list. If index equals the length of the linked list, the node will be appended to the end of the linked list. If index is greater than the length, the node will not be inserted.
- void deleteAtIndex(int index) Delete the indexth node in the linked list, if the index is valid.

Example 1:

Input
 ["MyLinkedList", "addAtHead", "addAtTail", "addAtIndex", "get", "deleteAtIndex", "get"]
 [[], [1], [3], [1, 2], [1], [1], [1]]
 Output
 [null, null, null, null, 2, null, 3]

Explanation
 MyLinkedList myLinkedList = new MyLinkedList();
 myLinkedList.addAtHead(1);
 myLinkedList.addAtTail(3);
 myLinkedList.addAtIndex(1, 2); // linked list becomes 1->2->3
 myLinkedList.get(1); // returns 2
 myLinkedList.deleteAtIndex(1); // now the linked list is 1->3
 myLinkedList.get(1); // returns 3

Constraints:

- 0 <= index, val <= 1000
- Please do not use the built-in LinkedList library.
- At most 2000 calls will be made to get, addAtHead, addAtTail, addAtIndex and deleteAtIndex.

Insert into a Sorted Circular Linked List
LeetCode · Linked List · Hash Table · LeetCode - Editorial
Linked List
Lists: Premium 98
Problem:
Given a Circular Linked List node, which is sorted in non-decreasing order, write a function to insert a value insertVal into the list such that it remains a sorted circular list. The given node can be a reference to any single node in the list and may not necessarily be the smallest value in the circular list.
If there are multiple suitable places for insertion, you may choose any place to insert the new value. After the insertion, the circular list should remain sorted.
If the list is empty (i.e., the given node is null), you should create a new single circular list and return the reference to that single node. Otherwise, you should return the originally given node.
Example 1:

```

# Definition for a Node.
class Node:
    def __init__(self, val, next=None):
        self.val = val
        self.next = next

class Solution:
    def insert(self, head: 'Node', insertVal: int) -> 'Node':
        # If the list is empty, create a new node pointing to itself and return it.
        if not head:
            newnode = Node(insertVal)
            newnode.next = newnode
            return newnode

        curr = head
        inserted = False

        while True:
            # Case 1: Insert between two nodes where insertVal is between curr.val and curr.next.val.
            if curr.val <= insertVal <= curr.next.val:
                inserted = True
                break

            # Case 2: curr.val > curr.next.val, i.e., we are at the turning point.
            # In this case, insert if insertVal is greater than curr.val (largest)
            # or insertVal is less than curr.next.val (smallest).
            elif curr.val > curr.next.val:
                if insertVal <= curr.val or insertVal >= curr.next.val:
                    inserted = True
                    break

            # If inserted:
            newnode = Node(insertVal, curr.next)
            curr.next = newnode
            return head

        curr = curr.next
        # If we have traversed the entire circle and come back to head, break.
        if curr == head:
            break

        # Case 3: All values are the same or no valid index was found, insert arbitrarily.
        newnode = Node(insertVal, curr.next)
        curr.next = newnode
        return head

Remove Zero Sum Consecutive Nodes from Linked List

LeetCode · Simplify in · HashCC · LeetCode · Editorial

Hash Table · Linked List

List: Denny Zhang

Problem:

Given the head of a linked list, we repeatedly delete consecutive sequences of nodes that sum to 0 until there are no such sequences.

After doing so, return the head of the final linked list. You may return any such answer.

(Note that in the examples below, all sequences are serializations of ListNode objects.)

Example 1:

Input: head = [1,2,-3,3,1]

Output: [3,1]

Note: The answer [1,2,1] would also be accepted.

Example 2:

Input: head = [1,2,3,-3,4]

Output: [1,2,4]

Example 3:

Input: head = [1,2,3,-3,-2]

Output: [1]

Constraints:

Linked List · LeetCode - By Pattern

— 1919 —

LeetCode

- The given linked list will contain between 1 and 1000 nodes.
- Each node in the linked list has $-1000 \leq \text{node.val} \leq 1000$.

Python

```

class ListNode:
    def __init__(self, val=0, next=None):
        self.val = val
        self.next = next

class Solution:
    def removeZeroSumSublists(self, head: ListNode) -> ListNode:
        # Create a dummy node to simplify cases where removal starts at the head.
        dummy = ListNode(0)
        dummy.next = head

        # Dictionary to store prefix sum to node mapping.
        sum_to_node = {}
        prefix_sum = 0
        current = dummy

        # First pass: record the last occurrence of each prefix sum.
        while current:
            prefix_sum += current.val
            sum_to_node[prefix_sum] = current
            current = current.next

        # Second pass: remove nodes that are part of zero-sum sequences.
        prefix_sum = 0
        current = dummy
        while current:
            prefix_sum += current.val
            # Skip current node's next pointer to skip the zero-sum subsequence.
            current.next = sum_to_node[prefix_sum].next
            current = current.next
        return dummy.next

#25 HARD
Reverse Nodes in k-Group
LeetCode · SimpleList · [WuMCC](#) · [LeetCode](#) · [Editorial](#)
[Linked List](#) · [Recursion](#)
List: Grind 169

Problem:
Given the head of a linked list, reverse the nodes of the list k at a time, and return the modified list.
k is a positive integer and is less than or equal to the length of the linked list. If the number of nodes is not a multiple of k then left-out nodes, in the end, should remain as it is.
You may not alter the values in the list's nodes, only nodes themselves may be changed.
Example 1:

Linked List · LeetCode - By Pattern

— 1931 —

LeetCode

Constraints:

- The number of nodes in the list is n.
- 1 ≤ k ≤ n ≤ 5000
- 0 ≤ Node.val ≤ 1000

Follow-up: Can you solve the problem in O(1) extra memory space?

#432 **HARD**
All O'one Data Structure
LeetCode · SimpleList · WsBCC · LeetCode · Editorial
Hash Table · Design · Doubly-Linked List · Linked List
Lists Dummy Zhang

Problem:

Design a data structure to store the strings' count with the ability to return the strings with minimum and maximum counts.

Implement the AllOne class:

- AllOne() Initializes the object of the data structure.
- inc(String key) Increments the count of the string key by 1. If key does not exist in the data structure, insert it with count 1.
- dec(String key) Decrements the count of the string key by 1. If the count of key is 0 after the decrement, remove it from the data structure. It is guaranteed that key exists in the data structure before the decrement.
- getMaxKey() Returns one of the keys with the maximal count. If no element exists, return an empty string "".
- getMinKey() Returns one of the keys with the minimal count. If no element exists, return an empty string "".

Note that each function must run in O(1) average time complexity.

Example 1:

```

Input
["AllOne", "inc", "inc", "getMaxKey", "getMinKey", "inc", "getMaxKey", "getMinKey"]
[[], ["hello"], ["hello"], [], [], ["leet"], [], []]
Output
[null, null, null, "hello", "hello", null, "hello", "leet"]

```

Explanation
AllOne allOne = new AllOne();
allOne.inc("hello");
allOne.inc("hello");
allOne.getMaxKey(); // return "hello"
allOne.getMinKey(); // return "hello"
allOne.inc("leet");
allOne.getMaxKey(); // return "hello"
allOne.getMinKey(); // return "leet"

Constraints:

- 1 <= key.length <= 10
- key consists of lowercase English letters.
- It is guaranteed that for each call to dec, key is existing in the data structure.
- At most 5 * 10^4 calls will be made to inc, dec, getMaxKey, and getMinKey.

LFU Cache

LeetCode · [Complexity](#) · [WalkCC](#) · [LeetCode](#) · [Editorial](#)

Hash Table · Linked List · Design · Doubly-Linked List

Lists Denny Zhang

Problem:

Design and implement a data structure for a Least Frequently Used (LFU) cache.

Implement the LFUCache class:

- LFUCache(int capacity) Initializes the object with the capacity of the data structure.
- int get(int key) Gets the value of the key if the key exists in the cache. Otherwise, returns -1.
- void put(int key, int value) Update the value of the key if present, or inserts the key if not already present. When the cache reaches its capacity, it should invalidate and remove the least frequently used key before inserting a new item. For this problem, when there is a tie (i.e., two or more keys with the same frequency), the least recently used key would be invalidated.

To determine the least frequently used key, a use counter is maintained for each key in the cache. The key with the smallest use counter is the least frequently used key.

When a key is first inserted into the cache, its use counter is set to 1 (due to the put operation). The use counter for a key in the cache is incremented either a get or put operation is called on it.

The functions get and put must each run in O(1) average time complexity.

Example 1:

```

Input
["LFUCache", "put", "put", "get", "put", "get", "get", "put", "get"]
[[2], [1, 1], [2, 2], [1], [3, 3], [2], [3], [4, 4], [1], [3], [4]]
Output
[null, null, null, 1, null, -1, 3, null, -1, 3, 4]

```

Explanation

```

// cnt[0] is the use counter for key x
// cache[i] will show the last used order for tiebreakers (leftmost element is most recent)
LFUCache lfu = new LFUCache(2);
lfu.put(1, 1); // cache[1]=1, cnt[1]=1
lfu.put(2, 2); // cache[2]=1, cnt[2]=1, cnt[1]=1
lfu.get(1); // returns 1
// cache[1]=2, cnt[2]=1, cnt[1]=2
lfu.put(3, 3); // 2 is the LFU key because cnt[2]=1 is the smallest, invalidate 1.

Space Complexity: O(capacity), storing key-node pairs and linked list nodes.

Solution

The solution combines a hash table (or dictionary) and a doubly linked list.

- The hash table stores keys and corresponding node addresses. - The doubly linked list maintains the order of usage with the most recently used items near the head. - For `get(key)`, check the dictionary. If found, move the node to the head and return its value; if not, return `-1`. - For `put(key, value)`, if the key exists, update its value and move it to the head. If not, create a new node and add it right after the head. If the capacity is reached, remove the tail node (least recently used) and update the dictionary accordingly. - Dummy head and tail nodes are used to simplify node addition and removal procedures without worrying about edge cases.

#148 Sort List [Medium]

Key Insights

- Merge sort is well-suited for linked lists; it naturally relies on splitting the list and merging sorted sublists.
- The slow and fast pointer technique is used to find the middle point of the list.
- A recursive merge sort implementation may use $O(\log n)$ space for recursion stack. To achieve $O(1)$ extra space, an iterative bottom-up merge sort approach would be preferred.
- Merging two sorted lists is efficient with linked lists because of their sequential access.

Space & Time

Time Complexity: $O(\log n)$

Space Complexity: $O(1)$ extra space for an iterative bottom-up approach ($O(\log n)$ for recursive calls if using recursion)

Solution

The solution employs the merge sort algorithm tailored for linked lists. The overall steps are:

- Use the slow and fast pointers to find the middle of the list and split it into two halves. - Recursively sort the two halves. - Merge the two sorted halves by comparing node values. - Ensure that during merging, pointers are adjusted properly to build the sorted list.

For an $O(1)$ space solution, an iterative bottom-up merge sort can be implemented. However, the recursive merge sort is easier to understand and implement, though it uses $O(\log n)$ space on the call stack.

#328 Odd Even Linked List [Medium]

Key Insights

- Use two pointers: one for odd-indexed nodes and one for even-indexed nodes.
- The first node is considered odd, and the second node is even.
- Traverse the list once, reassigning the next pointers to segregate odd and even nodes.
- Finally, attach the even list at the end of the odd list.
- The solution must use $O(1)$ extra space and $O(n)$ time complexity.

Space & Time

Time Complexity: $O(n)$ since the list is traversed once.

Space Complexity: $O(1)$ as only a few pointers are used.

Solution

Maintain two pointers, odd and even, starting from the head and `head.next`, respectively. As you iterate, update `odd.next` to point to the next odd element (skipping an even node) and `even.next` to point to the next even element. Once the end is reached, attach the even list to the end of the odd list. This in-place rearrangement preserves the initial ordering within odd and even groups while meeting the space and time constraints.

#369 Plus One Linked List [Medium]

Key Insights

Linked List · LeetCode · By Pattern — 1975 — LeetCode

dequeuing, we remove the element at the front index and increment the front pointer modulo the size. The counter helps in quickly checking if the queue is empty or full (count equals 0 or count equals capacity, respectively). This design ensures all operations remain $O(1)$ and correctly wraps around, forming a circular structure.

#707 Design Linked List [Medium]

Key Insights

- Use a dummy head node to simplify insertion and deletion at the head.
- Maintain a size counter to quickly validate index-based operations.
- For every operation, traverse the list up to the required point since random access is not available.
- Ensure robustness by handling edge cases like negative indices and indices larger than the current length.

Space & Time

Time Complexity:

- `get`, `addAtIndex`, and `deleteAtIndex` operations require $O(n)$ time due to the need to traverse the list.
 - `addAtHead` and `addAtTail` (if tail pointer is not maintained) are $O(n)$ in worst case; however, these can be optimized further if a tail pointer is added.
- Space Complexity:
- $O(n)$ space for storing n nodes.

Solution

The solution employs a singly linked list with a dummy head node to ease edge-case handling. A size counter is maintained for quick index validations. Each node holds a value and a pointer to the next node. Operations operate by traversing the list to the correct insertion or deletion point. This design makes it simple to add the functionality of getting values, inserting at specified indices, and removing nodes.

#708 Insert into a Sorted Circular Linked List [Medium]

Key Insights

- Handle the empty list edge-case by creating a new node that points to itself.
- Traverse the list until the proper insertion point is found.
- Consider the "turning point" where the maximum value is followed by the minimum value.
- If no proper place is found in one full rotation, insert the new node arbitrarily (e.g., after the head).

Space & Time

Time Complexity: $O(n)$ in the worst-case when a full loop is required.

Space Complexity: $O(1)$ since we only use a few extra pointers.

Solution

We traverse the circular linked list starting from the arbitrary given node. For each pair of consecutive nodes (`curr` and `next`), we check if the new value can be inserted between them by confirming that:

- The new value lies between `curr.val` and `next.val` (i.e., `curr.val <= insertVal <= next.val`). - Or if we are at the pivot point where the minimum value meets the maximum value (i.e., `curr.val > next.val`) and then either the new value is larger than or equal to `curr.val` (should be appended after the maximum) or less than or equal to `next.val` (should be inserted before the minimum).

If no proper spot is found after one complete loop, we insert anywhere (all values in the list are the same). A pointer reference is updated accordingly to maintain the circular structure.

#1171 Remove Zero Sum Consecutive Nodes from Linked List [Medium]

Key Insights

- Use a dummy node to handle edge cases such as the removal of nodes at the head.
- Compute a running `prefixSum` while traversing the list.
- Use a hash table (or hashmap) to map each prefix sum to the most recent node where that sum occurred.

Linked List · LeetCode · By Pattern — 1977 — LeetCode

position. Removal of a key from a node and deletion of empty nodes ensures that `getMinKey()` and `getMaxKey()` can be returned directly from the head and tail of the DLL.

#460 LFU Cache [Hard]

Key Insights

- Maintain a mapping from key to its value and frequency.
- Use an additional mapping from frequency to keys (maintaining the order of insertion or recent use) for quick eviction.
- Keep a global `minFreq` variable to track the lowest frequency present in the cache.
- When a key is accessed or updated, increase its frequency and relocate it in the frequency mapping.
- Evictions occur by removing the oldest key from the lowest frequency bucket.

Space & Time

Time Complexity: $O(1)$ average for both get and put.

Space Complexity: O(capacity), where capacity is the maximum number of keys stored.

Solution

The solution utilizes two main data structures:

- A hash map (`keyToValFreq`) that maps keys to a pair (value, frequency). - A second hash map (`freqToKeys`) mapping frequencies to an ordered list/set of keys. This data structure preserves the order in which keys were added to allow removal of the least recently used key when multiple keys share the same frequency.

A global `minFreq` variable is maintained to quickly identify the bucket with the least frequency. When a key is accessed or updated, the key is removed from its current frequency list and placed in the next higher frequency list. If the frequency list for the minimal frequency becomes empty, `minFreq` is updated.

This design guarantees that both get and put operations execute in constant time on average.

Linked List · LeetCode · By Pattern — 1979 — LeetCode

- The digits are stored such that the most significant digit comes first, but addition is easier starting from the least significant digit.
- Reversing the list allows simpler management of the carry during addition.
- After processing the addition, reversing the list back restores the original order.
- Consider special cases where all digits are 9, requiring a new head node to accommodate an additional digit.

Space & Time

Time Complexity: $O(n)$, where n is the number of nodes in the list.

Space Complexity: $O(1)$ extra space when using an iterative reversal method. $O(n)$ if recursion is used!

Solution

We solve the problem by first reversing the linked list, which converts it to a format where the least significant digit is processed first. We then iterate over the reversed list, adding one and managing any carry. If we encounter a carry at the end of the list, a new node is appended to handle the overflow. Finally, we reverse the list again to restore the original order. This method efficiently handles the addition with constant extra space during processing.

#430 Flatten a Multilevel Doubly Linked List [Medium]

Key Insights

- Use a depth-first traversal to process child lists before proceeding to the next pointer.
- When a node with a child is found, recursively flatten the child list.
- Splice the flattened child list in between the current node and the next node.
- Maintain previous and next pointers correctly to preserve the doubly linked list properties.
- Ensure that all child pointers are set to null after flattening.

Space & Time

Time Complexity: $O(n)$, where n is the total number of nodes, since each node is processed exactly once.

Space Complexity: $O(n)$ in the worst-case due to recursion stack in case of a highly nested list.

Solution

We can solve this problem using a recursive depth-first search (DFS) approach. The main idea is to traverse the list and, whenever a node with a child pointer is encountered, recursively flatten its child list. Once the child list is flattened, it can be spliced into the main list between the current node and the node originally following it. We then continue processing the next pointer. This ensures that the entire list is flattened in depth-first order. The recursive helper function returns the tail of the flattened segment, which is used to connect the subsequent parts of the list correctly.

#622 Design Circular Queue [Medium]

Key Insights

- Leverage a fixed-size array to store the queue elements.
- Use two pointers: one for the front and one for the rear.
- Maintain a count variable (or use pointer arithmetic) to differentiate between an empty and a full queue.
- Use modulo arithmetic to wrap pointers when they reach the end of the array.
- Ensure all operations (`enQueue`, `deQueue`, `Front`, `Rear`, `isEmpty`, `isFull`) have $O(1)$ time complexity.

Space & Time

Time Complexity: $O(1)$ per operation for `enQueue`, `deQueue`, `Front`, `Rear`, `isEmpty`, and `isFull`.

Space Complexity: $O(k)$, where k is the capacity of the circular queue.

Solution

We implement the circular queue using a fixed-size array alongside two pointers, `front` and `rear`, and a counter to keep track of the number of elements in the queue. The `front` pointer indicates the first element, and the `rear` pointer indicates the index where the next element will be enqueued. When enqueueing an element, we increment the `rear` index and then increment the `rear` pointer modulo the size of the array. Similarly, when

Linked List · LeetCode · By Pattern — 1976 — LeetCode

- If the same prefix sum is encountered again, the nodes in between sum to 0 and can be removed by adjusting pointers.
- Perform two passes: the first to record prefix sums and their corresponding nodes, and the second to remove zero-sum sequences.

Space & Time

Time Complexity: $O(n)$ - Two passes over the list.

Space Complexity: $O(n)$ - Hash table storing at most n prefix sums.

Solution

The solution uses a two-pass algorithm with a hash table. In the first pass, compute the prefix sum for each node and store the mapping from prefix sum to the node (overwriting with the latest occurrence). This ensures that for any repeated prefix sum, the nodes in between sum to 0. In the second pass, traverse the list again and use the hash table to skip the zero-sum subsequences by redirecting the next pointer of a node to the next pointer of the stored node for that prefix sum. Key data structures are the hash table and a dummy node to simplify pointer adjustments.

#25 Reverse Nodes in k-Group [Hard]

Key Insights

- Use a dummy node to simplify edge cases.
- Identify groups of k nodes using a helper function.
- Reverse the nodes in each group using pointer manipulation.
- If a remaining group has fewer than k nodes, leave it unchanged.
- The reversal is done in-place with $O(1)$ extra space.

Space & Time

Time Complexity: $O(n)$ where n is the number of nodes (each node is processed a constant number of times)

Space Complexity: $O(1)$ (only constant extra space is used)

Solution

The solution involves iterating through the linked list by identifying groups of k consecutive nodes. For each group: Find the k th node from the current starting point. If it does not exist, the remainder of the list is not reversed. Reverse the nodes in the identified group in-place by adjusting the next pointers. - Reconnect the reversed group with the previous part of the list and update pointers to move to the next group. The approach leverages a dummy node for easier handling of head modifications and uses a helper function to fetch the k th node. The in-place reversal ensures that the extra memory usage is constant.

#432 All O'one Data Structure [Hard]

Key Insights

- Use a Doubly-Linked List (DLL) where each node holds a unique count value and a set of keys with that count.
- Maintain a Hash Map (`keyToNode`) to quickly locate the node corresponding to each key.
- Insert new nodes in the DLL when a key's count is incremented or decremented and the adjacent node does not have the target count.
- Remove nodes from the DLL when no keys remain in that count.
- The head of the DLL holds the minimum count and the tail holds the maximum count.

Space & Time

Time Complexity: $O(1)$ average for `inc`, `dec`, `getMaxKey`, and `getMinKey`.

Space Complexity: $O(n)$ where n is the number of unique keys in the data structure.

Solution

The solution uses a combination of a doubly-linked list and hash maps. Each node in the DLL represents a frequency and maintains a set of keys that have that frequency. A hash map maps keys to their corresponding node. When `inc(key)` or `dec(key)` is called, we update the key's frequency and move the key to the appropriate node in the DLL. If the adjacent node with the required frequency doesn't exist, we create a new node and insert it in the correct

Island Perimeter

LeetCode · SimpleLen · WalkCCC · LeetCode · Editorial

Array · DFS · BFS · Matrix

List: Donny Zhang

Problem:

You are given row x col grid representing a map where `grid[i][j] == 1` represents land and `grid[i][j] == 0` represents water.

Grid cells are connected horizontally/vertically (not diagonally). The grid is completely surrounded by water, and there is exactly one island (i.e., one or more connected land cells).

The island doesn't have "lakes", meaning the water inside isn't connected to the water around the island. One cell is a square with side length 1. The grid is rectangular, with width and height don't exceed 100. Determine the perimeter of the island.

Example 1:

Input: grid = [[0,1,0,0],[1,1,1,0],[0,1,0,0],[1,1,0,0]]

Output: 16

Explanation: The perimeter is the 16 yellow stripes in the image above.

Example 2:

Input: grid = [[1]]

Output: 4

Example 3:

Input: grid = [[1,0]]

Output: 4

Linked List · LeetCode · By Pattern — 1980 — LeetCode

Constraints:

- row == grid.length
- col == grid[0].length
- 1 <= row, col <= 100
- grid[i][j] is 0 or 1.
- There is exactly one island in grid.

Flood Fill

LeetCode · [SimplifyLeet](#) · [WalkCC](#) · [LeetCode](#) · [Editorial](#)

Array · DFS · BFS · Matrix

Lists Grid 189

Problem:

You are given an image represented by an $m \times n$ grid of integers image, where image[i][j] represents the pixel value of the image. You are also given three integers sr, sc, and color. Your task is to perform a flood fill on the image starting from the pixel image[sr][sc].

To perform a flood fill:

1. Begin with the starting pixel and change its color to color.
2. Perform the same process for each pixel that is directly adjacent (pixels that share a side with the original pixel, either horizontally or vertically) and shares the same color as the starting pixel.
3. Keep repeating this process by checking neighboring pixels of the updated pixels and modifying their color if it matches the original color of the starting pixel.
4. The process stops when there are no more adjacent pixels of the original color to update.

Return the modified image after performing the flood fill.

Example 1:

Input: image = [[1,1,1],[1,1,0],[1,0,1]], sr = 1, sc = 1, color = 2

Output: [[2,2,2],[2,2,0],[2,0,1]]

Explanation:

From the center of the image with position (sr, sc) = (1, 1) (i.e., the red pixel), all pixels connected by a path of the same color as the starting pixel (i.e., the blue pixels) are colored with the new color. Note the bottom corner is not colored 2, because it is not horizontally or vertically connected to the starting pixel.

Example 2:

Input: image = [[0,0,0],[0,0,0]], sr = 0, sc = 0, color = 0

Output: [[0,0,0],[0,0,0]]

Explanation:

The starting pixel is already colored with 0, which is the same as the target color. Therefore, no changes are made to the image.

Constraints:

- $m == \text{image.length}$
- $n == \text{image}[0].\text{length}$
- $1 \leq m, n \leq 50$
- $0 \leq \text{image}[i][j], \text{color} < 216$
- $0 \leq sr < m$
- $0 \leq sc < n$

>> Brute Force [DFS] Interview Prep

Surrounded Regions

LeeMastery · Simplicity · LeetCode · Editorial

DFS · LeeMastery — By Pattern

— 1998 —

LeeMastery

Problem:

You are given an m x n matrix board containing letters 'X' and 'O', capture regions that are surrounded:

- Connect: A cell is connected to adjacent cells horizontally or vertically.
- Region: To form a region connect every 'O' cell.
- Surround: A region is surrounded if none of the 'O' cells in that region are on the edge of the board. Such regions are completely enclosed by 'X' cells.

To capture a surrounded region, replace all 'O's with 'X's in-place within the original board. You do not need to return anything.

Example 1:

Input: board = `[["X","X","X","X"],["X","O","X","X"],["X","X","O","X"],["X","O","X","X"]]`

Explanation:

In the above diagram, the bottom region is not captured because it is on the edge of the board and cannot be surrounded.

Example 2:
Input: board = `[["X"]]`
Output: `[["X"]]`

Constraints:

- m == board.length
- n == board[0].length
- 1 <= m, n <= 200
- board[i][j] is 'X' or 'O'.

Clone Graph

LeetCode · Interview · WalkCC · LeetCode · Editorial

Hash Table · DFS · BFS · Graph

Lists Grind 169

Problem:

Given a reference of a node in a connected undirected graph.

Return a deep copy (clone) of the graph.

Each node in the graph contains a value (int) and a list (List(Node)) of its neighbors.

```

class Node {
public:
    int val;
    List<Node> neighbors;
};
```

Test case format:

For simplicity, each node's value is the same as the node's index (1-indexed). For example, the first node with val = 1, the second node with val = 2, and so on. The graph is represented in the test case using an adjacency list.

An adjacency list is a collection of unordered lists used to represent a finite graph. Each list describes the set of neighbors of a node in the graph.

The given node will always be the first node with val = 1. You must return the copy of the given node as a reference to the cloned graph.

Example 1:

Input: adjList = [[2,4],[1,3],[2,4],[1,3]]

Output: [[2,4],[1,3],[2,4],[1,3]]

Explanation: There are 4 nodes in the graph.

1st node (val = 1)'s neighbors are 2nd node (val = 2) and 4th node (val = 4).

2nd node (val = 2)'s neighbors are 1st node (val = 1) and 3rd node (val = 3).

3rd node (val = 3)'s neighbors are 2nd node (val = 2) and 4th node (val = 4).

4th node (val = 4)'s neighbors are 1st node (val = 1) and 3rd node (val = 3).

Example 2:

Input: adjList = [[]]

Output: [[]]

Explanation: Note that the input contains one empty list. The graph consists of only one node with val = 1 and it does not have any neighbors.

Example 3:

Input: adjList = []

Output: []

Explanation: This an empty graph, it does not have any nodes.

Constraints:

- The number of nodes in the graph is in the range [0, 100].
- $1 \leq \text{Node.val} \leq 100$
- Node.val is unique for each node.
- There are no repeated edges and no self-loops in the graph.
- The Graph is connected and all nodes can be visited starting from the given node.

Python

Python

```

Number of Islands

LeetCode · LeetCode · LeetCode · Editorial

Array · DFS · BFS · Union Find · Matrix

Lists · Grid · 169

Problem:

Given an $m \times n$ 2D binary grid grid which represents a map of '1's (land) and '0's (water), return the number of islands.

An island is surrounded by water and is formed by connecting adjacent lands horizontally or vertically. You may assume all four edges of the grid are all surrounded by water.

Example 1:

```

Input: grid = [
  ["1","1","1","1","0"],
  ["1","1","0","1","0"],
  ["1","1","0","1","0"]
]

```

DPS · LeetCode · By Pattern — 2024 — LeetCode

```

["1","1","0","0","0"],
["0","0","0","0","0"]
]
Output: 1
Example 2:
Input: grid = [
  ["1","1","0","0","0"],
  ["1","1","0","0","0"],
  ["0","0","1","0","0"],
  ["0","0","0","1","1"]
]
Output: 3
Constraints:
• m == grid.length
• n == grid[0].length
• 1 <= m, n <= 300
• grid[i][j] is '0' or '1'.

Course Schedule

LeetCode · Simplify · WalkCC · LeetCode · Editorial

DPS · BFS · Graph · Topological Sort

Units Grind 189

Problem:

There are a total of `numCourses` courses you have to take, labeled from `0` to `numCourses - 1`. You are given an array `prerequisites` where `prerequisites[i] = [ai, bi]` indicates that you must take course `bi` first if you want to take course `ai`.

• For example, the pair `[0, 1]`, indicates that to take course `0` you have to first take course `1`.

Return `true` if you can finish all courses. Otherwise, return `false`.

Example 1:

Input: `numCourses = 2, prerequisites = [[1,0]]`

Output: `true`

Explanation: There are a total of 2 courses to take. To take course 1 you should have finished course 0. So it is possible.

Example 2:

Input: `numCourses = 2, prerequisites = [[1,0],[0,1]]`

Output: `false`

Explanation: There are a total of 2 courses to take. To take course 1 you should have finished course 0, and to take course 0 you should also have finished course 1. So it is impossible.

Constraints:

- `1 <= numCourses <= 2000`
- `0 <= prerequisites.length <= 5000`
- `prerequisites[i].length == 2`
- `0 <= ai, bi < numCourses`
- All the pairs `prerequisites[i]` are unique.

[*] DPS - Pattern Solution (stored optimal)

Python

```
from collections import deque

def canFinish(numCourses, prerequisites):
    # Create a list to store the number of prerequisites (indegree) for each course.
    indegree = [0] * numCourses
    # Create an adjacency list for each course.
    graph = [[] for i in range(numCourses)]

    # Build the graph and update indegree for each course.
    for course, prereq in prerequisites:
        graph[course].append(prereq)
        indegree[prereq] += 1

    # Initialize a queue with courses that have no prerequisites.
    queue = deque([i for i in range(numCourses) if indegree[i] == 0])

    # Counter for courses that can be completed.
    visited = 0

    while queue:
        course = queue.popleft() # Remove course with no remaining prerequisites.
        visited += 1 # Increment count of completed courses.
        # For each neighbor course, reduce its indegree.
        for neighbor in graph[course]:
            indegree[neighbor] -= 1 # Remove dependency.

        # If no more prerequisites, add to queue.
        if indegree[neighbor] == 0:
            queue.append(neighbor)

    # If we processed all courses, it's possible to finish.
    return visited == numCourses

# Example usage:
print(canFinish(2, [[1,0]])) # Expected output: True
print(canFinish(2, [[1,0],[0,1]])) # Expected output: False
```

C++

```
// C++ solution using DFS (Backtracking Algorithm)
#include <iostream>
#include <vector>
#include <queue>
using namespace std;

class Solution {
public:
    bool canFinish(int numCourses, vector<vector<int>>& prerequisites) {
        // Create an adjacency list for each course.
        vector<int> indegree(numCourses, 0);
        // adjacency list for the graph.
        vector<vector<int>> graph(numCourses);

        // Build the graph.
        for (auto& pre : prerequisites) {
            int course = pre[0], prereq = pre[1];
            graph[prereq].push_back(course);
            indegree[course]++;
        }

        // Queue for courses with no prerequisites.
        queue<int> q;
        for (int i = 0; i < numCourses; i++) {
            if (indegree[i] == 0) {
                q.push(i);
            }
        }

        int visited = 0;
        // Process courses.
        while (!q.empty()) {
            int course = q.front();
            q.pop();
            visited++;
            // Decrease indegree for each neighboring course.
            for (int neighbor : graph[course]) {
                indegree[neighbor]--;
                // If no prerequisites left, add neighbor to queue.
                if (indegree[neighbor] == 0) {
                    q.push(neighbor);
                }
            }
        }

        // If all courses are visited, return true.
        return visited == numCourses;
    }
};
```

```
// Example usage:
int main() {
    Solution sol;
    vector<vector<int>> prerequisites = {{1,0},
    vector<vector<int>> prerequisites = {{1,0}, {0,1}};
    cout << hasCycle(sol.canFinish(2, prerequisites)) << endl; // Expected output: true
    cout << hasCycle(sol.canFinish(2, prerequisites)) << endl; // Expected output: false
    return 0;
}
```

Like Grind 189

Problem:

There are a total of numCourses courses you have to take, labeled from 0 to numCourses - 1. You are given an array prerequisites where prerequisites[i] = [a, b] indicates that you must take course b first if you want to take course a.

• For example, the pair [0, 1], indicates that to take course 0 you have to first take course 1. Return the ordering of courses you should take to finish all courses. If there are many valid answers, return any of them. If it is impossible to finish all courses, return an empty array.

Example 1:

Input: numCourses = 2, prerequisites = [[1,0]]

Output: [0,1]

Explanation: There are a total of 2 courses to take. To take course 1 you should have finished course 0. So the correct course order is [0,1].

Example 2:

Input: numCourses = 4, prerequisites = [[1,0],[2,0],[3,1],[3,2]]

Output: [0,2,1,3]

Explanation: There are a total of 4 courses to take. To take course 3 you should have finished both courses 1 and 2. Both courses 1 and 2 should be taken after you finished course 0.

So one correct course order is [0,1,2,3]. Another correct ordering is [0,2,1,3].

Example 3:

Input: numCourses = 1, prerequisites = []

Output: [0]

Constraints:

- 1 <= numCourses <= 2000
- 0 <= prerequisites.length <= numCourses * (numCourses - 1)
- prerequisites[i].length == 2
- 0 <= a, b < numCourses

Graph Valid Tree

LeetCode · SimplyLeet · WalkCC · LeetCode · Editorial

DFS · BFS · Union Find · Graph

Lint-Grind ID: Premium 50

Problem:

You have a graph of n nodes labeled from 0 to $n - 1$. You are given an integer n and a list of edges where $edges[i] = [a_i, b_i]$ indicates that there is an undirected edge between nodes a_i and b_i in the graph.

Return true if the edges of the given graph make up a valid tree, and false otherwise.

Example 1:

Input: $n = 5$, $edges = [[0,1],[0,2],[0,3],[1,4]]$
Output: true

Example 2:

Input: $n = 5$, $edges = [[0,1],[1,2],[2,3],[1,4],[3,4]]$
Output: false

Constraints:

- $1 \leq n \leq 2000$
- $0 \leq edges.length \leq 5000$
- $edges[i].length = 2$

- $0 \leq a_i, b_i < n$
- $a_i \neq b_i$
- There are no self-loops or repeated edges.

>> Brute Force [DFS] Interview Prep

```
Python
# Brute Force Approach
class Solution:
    def validTree(self, n: int, edges: List[List[int]]) -> bool:
        # Create parent -> DFS from every unvisited node
        visited = set()
        count = 0
        def dfs(node):
            visited.add(node)
            for ab in graph.get(node, []):
                if ab not in visited:
                    dfs(ab)
            for node in range(n):
                if node not in visited:
                    dfs(node); count += 1
            return count

        You have to consider that accepts current node and its parent node
        def dfs(node, parent):
            # Add the current node to visited
            visited.add(node)
            # Traverse all the neighboring nodes
            for neighbor in graph[node]:
                # Skip the neighbor if it is the parent to avoid trivial cycle detection
                if neighbor == parent:
                    continue
                # If neighbor is already visited, a cycle is detected
```

```
Python
# Python solution with DFS
def validTree(n, edges):
    # If the number of edges is not exactly n - 1, it cannot be a tree
    if len(edges) != n - 1:
        return False

    # Build the graph as an adjacency list
    graph = [[] for i in range(n)]
    for a, b in edges:
        graph[a].append(b)
        graph[b].append(a)

    visited = set()

    # DFS helper function that accepts current node and its parent node
    def dfs(node, parent):
        # Add the current node to visited
        visited.add(node)
        # Traverse all the neighboring nodes
        for neighbor in graph[node]:
            # Skip the neighbor if it is the parent to avoid trivial cycle detection
            if neighbor == parent:
                continue
            # If neighbor is already visited, a cycle is detected
```

```

Minimum Height Trees

LeetCode · SimplifyLeetCode · WalkCC · LeetCode · Editorial

DFS · BFS · Graph · Topological Sort

Line: 61 of 109

Problem:

A tree is an undirected graph in which any two vertices are connected by exactly one path. In other words, any connected graph without simple cycles is a tree.

Given a tree of n nodes labelled from 0 to $n - 1$, and an array of $n - 1$ edges where $edges[i] = [a_i, b_i]$ indicates that there is an undirected edge between the two nodes a_i and b_i in the tree, you can choose any node of the tree as the root. When you select a node x as the root, the result tree has height h . Among all possible rooted trees, those with minimum height (i.e. $\min(h)$) are called minimum height trees (MHTs).

Return a list of all MHTs' root labels. You can return the answer in any order.

The height of a rooted tree is the number of edges on the longest downward path between the root and a leaf.

Example 1:

DFS · LeetCode · By Pattern

— 2078 —

LeetCode

Explanation: As shown, the height of the tree is 1 when the root is the node with label 1 which is the only MHT.

Example 2:

Input: $n = 6$, $edges = [[3,0],[3,1],[3,2],[3,4],[5,4]]$
Output: $[3,4]$

Constraints:

- $1 \leq n \leq 2 \cdot 10^4$
- $edges.length == n - 1$
- $0 \leq a_i, b_i < n$
- $a_i \neq b_i$
- All the pairs (a_i, b_i) are distinct.
- The given input is guaranteed to be a tree and there will be no repeated edges.

#323 **MEDIUM**
Number of Connected Components in an Undirected Graph
[LeetCode](#) · [SimplyList](#) · [WalkCC](#) · [LeetCode](#) · [Editorial](#)

DFS · BFS · Union Find · Graph
 Linux Cloud 100 · Premium 50

Problem:
 You have a graph of n nodes. You are given an integer n and an array edges where $edges[i] = [a_i, b_i]$ indicates that there is an edge between a_i and b_i in the graph.

DFS · LeetCodeMastery — By Pattern — 2089 — LeetCodeMastery

- $a_i \neq b_i$
- There are no repeated edges.

DFS · LeetCodeMastery — By Pattern — 2093 — LeetCodeMastery

Return the number of connected components in the graph.

Example 1:

Input: n = 5, edges = [[0,1],[1,2],[3,4]]

Output: 2

Example 2:

Input: n = 5, edges = [[0,1],[1,2],[2,3],[3,4]]

Output: 1

Constraints:

- $1 \leq n \leq 2000$
- $1 \leq edges.length \leq 5000$
- $edges[i].length == 2$
- $0 \leq a_i < b_i < n$

Pacific Atlantic Water Flow

LeetCode · Simplest · Rust · LeetCode · Editorial

Array · DFS · BFS · Matrix

Like Grind 109

Problem:

There is an $m \times n$ rectangular island that borders both the Pacific Ocean and Atlantic Ocean. The Pacific Ocean touches the island's left and top edges, and the Atlantic Ocean touches the island's right and bottom edges.

The island is partitioned into a grid of square cells. You are given an $m \times n$ integer matrix heights where heights[i][j] represents the height above sea level of the cell at coordinate (i, j).

The island receives a lot of rain, and the rain water can flow to neighboring cells directly north, south, east, and west if the neighboring cell's height is less than or equal to the current cell's height. Water can flow from any cell adjacent to an ocean into the ocean.

Return a 2D list of grid coordinates result where result[i] = [ri, ci] denotes that rain water can flow from cell (ri, ci) to both the Pacific and Atlantic oceans.

Example 1:

Pacific Ocean						
	1	2	2	3	5	
Pacific	3	2	3	4	4	Atlantic
Ocean	2	4	5	3	1	Ocean
	6	7	1	4	5	
	5	1	1	2	4	
Atlantic Ocean						

Input: heights = [[1,2,3,5],[2,3,4,4],[2,4,5,3],[6,7,1,4],[5,1,1,2,4]]

Output: [[0,4],[1,2],[1,4],[2,2],[3,0],[3,1],[4,0]]

Explanation: The following cells can flow to the Pacific and Atlantic oceans, as shown below:

- [0,4] → Atlantic Ocean
- [1,3]: [1,3] → [0,3] → Pacific Ocean
- [1,3] → [1,4] → Atlantic Ocean
- [1,4]: [1,4] → [1,3] → [0,3] → Pacific Ocean
- [1,4] → Atlantic Ocean
- [2,2]: [2,2] → [1,2] → [0,2] → Atlantic Ocean
- [2,2] → [2,3] → [2,4] → Atlantic Ocean
- [3,0]: [3,0] → Pacific Ocean
- [3,0] → [4,0] → Atlantic Ocean
- [3,1]: [3,1] → [3,0] → Pacific Ocean
- [3,1] → [4,1] → Atlantic Ocean
- [4,0]: [4,0] → Pacific Ocean
- [4,0] → Atlantic Ocean

Note that there are other possible paths for these cells to flow to the Pacific and Atlantic oceans.

Example 2:

Input: heights = [[1]]

Output: [[0,0]]

Explanation: The water can flow from the only cell to the Pacific and Atlantic oceans.

Constraints:

- $m == \text{heights.length}$

```
• m == heights[0].length
• 1 <= m, n <= 200
• 0 <= heights[i][j] <= 105

Array · DFS · BFS · Matrix

LeetCode Premium 98

DPS · LeeMastery — By Pattern

— 2114 —

LeeMastery

Problem:

There is a ball in a maze with empty spaces (represented as 0) and walls (represented as 1). The ball can go through the empty spaces by rolling up, down, left or right, but it won't stop rolling until hitting a wall. When the ball stops, it could choose the next direction.

Given the m x n maze, the ball's start position and the destination, where start = [startrow, startcol] and destination = [destinationrow, destinationcol], return true if the ball can stop at the destination, otherwise return false.

You may assume that the borders of the maze are all walls (see examples).

Example 1:

Input: maze = [[0,0,1,0,0],[0,0,0,0,0],[0,0,0,1,0],[1,1,0,1,1],[0,0,0,0,0]], start = [0,4], destination = [4,4]

Output: true

Explanation: One possible way is : left -> down -> left -> down -> right -> down -> right.

Example 2:

DPS · LeeMastery — By Pattern

— 2115 —

LeeMastery

Input: maze = [[0,0,1,0,0],[0,0,0,0,0],[0,0,0,1,0],[1,1,0,1,1],[0,0,0,0,0]], start = [0,4], destination = [2,2]

Output: false

Explanation: There is no way for the ball to stop at the destination. Notice that you can pass through the destination but you cannot stop there.

Example 3:

Input: maze = [[0,0,0,0,0],[1,1,0,0,1],[0,0,0,0,0],[0,1,0,0,1],[0,1,0,0,0]], start = [4,3], destination = [0,1]

Output: false

Constraints:

- m == maze.length
- n == maze[0].length
- 1 <= m, n <= 100
- maze[i][j] is 0 or 1.
- start.length == 2
- destination.length == 2
- 0 <= startrow, destinationrow < m
- 0 <= startcol, destinationcol < n
- Both the ball and the destination exist in an empty space, and they will not be in the same position initially.
- The maze contains at least 2 empty spaces.

Number of Distinct Islands

LeetCode · SimplifyLear · WalkCC · LeetCode · Editorial

Hash Table · DFS · BFS · Union Find · Hash Function

Little Premium 98

Problem:

You are given an $m \times n$ binary matrix grid. An island is a group of 1's (representing land) connected 4-directionally (horizontal or vertical). You may assume all four edges of the grid are surrounded by water.

An island is considered to be the same as another if and only if one island can be translated (and not rotated or reflected) to equal the other.

Return the number of distinct islands.

Example 1:

1	1	0	0	0
1	1	0	0	0
0	0	0	1	1
0	0	0	1	1

Input: grid = [[1,1,0,0,0],[1,1,0,0,0],[0,0,0,1,1],[0,0,0,1,1]]

Output: 1

Example 2:

1	1	0	1	1
1	0	0	0	0
0	0	0	0	1
1	1	0	1	1

Input: grid = [[1,1,0,1,1],[1,0,0,0,0],[0,0,0,1,1],[1,1,0,1,1]]

Output: 3

Constraints:

- $m == \text{grid.length}$
- $n == \text{grid}[i].\text{length}$
- $1 \leq m, n \leq 50$
- grid[i][j] is either 0 or 1.

[*] DPS — Pattern Solution (masched from community answers)

Python

```

def numDistinctIslands(grid):
    # Get the number of rows and columns
    rows, cols = len(grid), len(grid[0])
    # Set to store unique island shapes
    distinct_shapes = set()

    # DFS function to explore the island and record its relative shape
    def dfs(r, c, orig_r, orig_c, shape):
        # Check boundaries and if the cell is unvisited land
        if r < 0 or c < 0 or r == rows or c == cols or grid[r][c] == 0:
            return
        # Mark the cell as visited by setting it to 0
        grid[r][c] = 0
        # Record the relative position from the origin of this island
        shape.append((r - orig_r, c - orig_c))
        # Explore all 4-directionally adjacent cells
        drs = [-1, 0, 1, 0], [0, 1, 0, -1]
        dfs(r + 1, c, orig_r, orig_c, shape)
        dfs(r - 1, c, orig_r, orig_c, shape)
        dfs(r, c + 1, orig_r, orig_c, shape)
        dfs(r, c - 1, orig_r, orig_c, shape)

    # Iterate over every cell in the grid
    for i in range(rows):
        for j in range(cols):
            if grid[i][j] == 1:
                shape = []
                dfs(i, j, i, j, shape)
                # Convert the shape list to a tuple of sorted coordinates for canonical form
                distinct_shapes.add(tuple(sorted(shape)))

    # The number of distinct islands is the size of the set
    return len(distinct_shapes)

# Example usage:
grid = [[1,1,0,0,1],
        [1,1,0,0,1],
        [0,0,0,1,1],
        [0,0,0,1,1]]
print(numDistinctIslands(grid)) # Output: 1

```

MEDIUM

Max Area of Island

LeetCode · Union-find · Math · DFS · LeeCode · Editorial

Array · DFS · BFS · Union Find · Matrix

Little Denny Zhang

Problem:

You are given an $m \times n$ binary matrix grid. An island is a group of 1's (representing land) connected 4-directionally (horizontal or vertical). You may assume all four edges of the grid are surrounded by water.

The area of an island is the number of cells with a value 1 in the island.

Return the maximum area of an island in grid. If there is no island, return 0.

Example 1:

0	0	1	0	0	0	0	1	0	0	0	0	0
0	0	0	0	0	0	0	1	1	0	0	0	0
0	1	1	0	1	0	0	0	0	0	0	0	0
0	1	0	0	1	1	0	0	1	0	1	0	0
0	1	0	0	1	1	0	0	1	1	1	0	0
0	0	0	0	0	0	0	0	0	0	1	0	0
0	0	0	0	0	0	0	1	1	1	0	0	0
0	0	0	0	0	0	0	1	1	0	0	0	0

Input: grid = [[0,0,1,0,0,0,0,0,1,0,0,0,0,0],[0,0,0,0,0,0,0,0,1,1,0,0,0],[0,1,0,0,1,0,0,0,0,0,0,0,0,0],[0,1,0,0,1,0,0,0,0,0,0,0,0,0],[0,0,0,0,0,0,0,0,0,0,0,0,0,0],[0,0,0,0,0,0,0,0,0,0,0,0,0,0],[0,0,0,0,0,0,0,0,0,0,0,0,0,0]]

Output: 6

Explanation: The answer is not 11, because the island must be connected 4-directionally.

Example 2:

Input: grid = [[0,0,0,0,0,0,0]]

Output: 0

Constraints:

- $m == \text{grid.length}$
- $n == \text{grid}[0].\text{length}$
- $1 \leq m, n \leq 50$
- $\text{grid}[i][j]$ is either 0 or 1.

#785 MEDIUM Is Graph Bipartite?

LeetCode · Simple Interview · Medium · LeetCode · Editorial

DFS · BFS · Union Find · Graph

Like Denny Zhang

Problem:

There is an undirected graph with n nodes, where each node is numbered between 0 and $n - 1$. You are given a 2D array `graph`, where `graph[u]` is an array of nodes that node u is adjacent to. More formally, for each v in `graph[u]`, there is an undirected edge between node u and node v . The graph has the following properties:

- There are no self-edges (`graph[u]` does not contain u).
- There are no parallel edges (`graph[u]` does not contain duplicate values).
- If v is in `graph[u]`, then u is in `graph[v]` (the graph is undirected).
- The graph may not be connected, meaning there may be two nodes u and v such that there is no path between them.

A graph is bipartite if the nodes can be partitioned into two independent sets A and B such that every edge in the graph connects a node in set A and a node in set B . Return `true` if and only if it is bipartite.

Example 1:

Input: `graph = [[1,2,3],[0,2],[0,1,3],[0,2]]`

Output: `false`

Explanation: There is no way to partition the nodes into two independent sets such that every edge connects a node in one and a node in the other.

Example 2:

Input: `graph = [[1,3],[0,2],[1,3],[0,2]]`

Output: `true`

Explanation: We can partition the nodes into two sets: $\{0, 2\}$ and $\{1, 3\}$.

Constraints:

- `graph.length == n`
- `1 <= n <= 100`
- `0 <= graph[u].length < n`
- `0 <= graph[u][i] < n - 1`
- `graph[u]` does not contain u .
- All the values of `graph[u]` are unique.
- If `graph[u]` contains v , then `graph[v]` contains u .

Web Crawler

LeetCode · Simple · WalkCC · LeetCode · Editorial

String · DFS · BFS · Interactive

LeetCode Premium 98

Problem:

Given a url startUrl and an interface HtmlParser, implement a web crawler to crawl all links that are under the same hostname as startUrl.

Return all urls obtained by your web crawler in any order.

Your crawler should:

- Start from the page: startUrl
- Call HtmlParser.getUrls(url) to get all urls from a webpage of given url.
- Do not crawl the same link twice.
- Explore only the links that are under the same hostname as startUrl.

http://example.org:8888/foo/bar#bang

hostname

As shown in the example url above, the hostname is example.org. For simplicity sake, you may assume all urls use http protocol without any port specified. For example, the urls http://leetcode.com/problems and http://leetcode.com/context are under the same hostname, while urls http://example.org/test and http://example.com/abc are not under the same hostname. The HtmlParser interface is defined as such:

```

interface HtmlParser {
    // Return a list of all urls from a webpage of given url.
    public List<String> getUrls(String url);
}

```

Below are two examples explaining the functionality of the problem, for custom testing purposes you'll have three variables urls, edges and startUrl. Notice that you will only have access to startUrl in your code, while urls and edges are not directly accessible to you in code.

Note: Consider the same URL with the trailing slash "/" as a different URL. For example, "http://news.yahoo.com", and "http://news.yahoo.com/" are different urls.

Example 1:

```

startUrl
http://news.yahoo.com/news/topics/
http://news.yahoo.com/
http://news.yahoo.com/us
http://news.google.com
http://news.yahoo.com/news

```

different hostname

different hostname

different hostname

Input:

```

urls = [
    "http://news.yahoo.com",
    "http://news.yahoo.com/news",
    "http://news.yahoo.com/news/topics/",
    "http://news.google.com"
]
edges = [[0,1],[1,2],[1,3],[2,3],[3,0]]
startUrl = "http://news.yahoo.com"
Output: ["http://news.yahoo.com", "http://news.yahoo.com/news", "http://news.yahoo.com/news/topics/"]
Explanation: The startUrl links to all other pages that do not share the same hostname.

```

Constraints:

- 1 <= urls.length <= 1000

```

"http://news.google.com",
"http://news.yahoo.com/us"
]
edges = [[0,1],[1,2],[1,3],[2,3],[3,0]]
startUrl = "http://news.yahoo.com/news/topics/"
Output: [
    "http://news.yahoo.com",
    "http://news.yahoo.com/news",
    "http://news.yahoo.com/news/topics/",
    "http://news.yahoo.com/us"
]

```

Example 2:

```

startUrl
http://news.google.com
http://news.yahoo.com/news/topics/
http://news.yahoo.com/news
http://news.yahoo.com/

```

different hostname

different hostname

different hostname

Input:

```

urls = [
    "http://news.yahoo.com",
    "http://news.yahoo.com/news",
    "http://news.yahoo.com/news/topics/",
    "http://news.google.com"
]
edges = [[0,2],[2,1],[3,2],[3,1],[3,0]]
startUrl = "http://news.google.com"
Output: ["http://news.google.com"]
Explanation: The startUrl links to all other pages that do not share the same hostname.

```

Constraints:

- 1 <= urls.length <= 1000

- `1 <= url[i].length <= 300`
- `startUrl` is one of the urls.
- Hostname label must be from 1 to 63 characters long, including the dots, may contain only the ASCII letters from 'a' to 'z', digits from '0' to '9' and the hyphen-minus character ('-').
- The hostname may not start or end with the hyphen-minus character ('-').
- See: https://en.wikipedia.org/wiki/Hostname#Restrictions_on_valid_hostnames
- You may assume there're no duplicates in url library.

Web Crawler Multithreaded

LeetCode · Simple Python · Walkthrough · LeetCode · Editorial

DPS · DFS · Concurrency

List: Denny Zhang

Problem:

Given a URL startUrl and an interface HtmlParser, implement a Multi-threaded web crawler to crawl all links that are under the same hostname as startUrl.

Return all URLs obtained by your web crawler in any order.

Your crawler should:

- Start from the page: startUrl

- Call HtmlParser.getUris(url) to get all URLs from a webpage of a given URL.
- Do not crawl the same link twice.
- Explore only the links that are under the same hostname as startUrl.

http://example.org:8888/foo/bar#bang

hostname

As shown in the example URL above, the hostname is example.org. For simplicity's sake, you may assume all URLs use HTTP protocol without any port specified. For example, the URLs http://leetcode.com/problems and http://leetcode.com/contest are under the same hostname, while URLs http://example.org/test and http://example.com/abc are not under the same hostname.

The HtmlParser interface is defined as such:

```

interface HtmlParser {
    // Return a list of all urls from a webpage of given url.
    // This is a blocking call, that means it will do HTTP request and return when this request is finished.
    public List<String> getUris(String url);
}

```

Note that getUris(String url) simulates performing an HTTP request. You can treat it as a blocking function call that waits for an HTTP request to finish. It is guaranteed that getUris(String url) will return the URLs within 15ms. Single-threaded solutions will exceed the time limit so, can your multi-threaded web crawler do better?

Below are two examples explaining the functionality of the problem. For custom testing purposes, you'll have three variables urls, edges and startUrl. Notice that you will only have access to startUrl in your code, while urls and edges are not directly accessible to you in code.

Example 1:

Input:

```

urls = [
    "http://news.yahoo.com",
    "http://news.yahoo.com/news",
    "http://news.yahoo.com/news/topics/",
    "http://news.google.com",
    "http://news.yahoo.com/us"
]
edges = [[2,8],[2,1],[3,2],[3,1],[8,4]]
startUrl = "http://news.yahoo.com/news/topics/"
Output: [
    "http://news.yahoo.com",
    "http://news.yahoo.com/news",
    "http://news.yahoo.com/news/topics/",
    "http://news.yahoo.com/us"
]

```

Example 2:

Input:
urls = [
 "http://news.yahoo.com",
 "http://news.yahoo.com/news",
 "http://news.yahoo.com/news/topics/",
 "http://news.google.com"
]
edges = [(0,2),(2,1),(3,2),(3,1),(3,0)]
startUrl = "http://news.google.com"
Output: ["http://news.google.com"]
Explanation: The startUrl links to all other pages that do not share the same hostname.

Constraints:

- 1 <= urls.length <= 1000
- 1 <= urls[i].length <= 300
- startUrl is one of the urls.
- Hostname label must be from 1 to 63 characters long, including the dots, may contain only the ASCII letters from 'a' to 'z', digits from '0' to '9' and the hyphen-minus character ('-').
- The hostname may not start or end with the hyphen-minus character ('-').
- See: https://en.wikipedia.org/wiki/Hostname#Restrictions_on_valid_hostnames
- You may assume there're no duplicates in the URL library.

Follow up:

1. Assume we have 10,000 nodes and 1 billion URLs to crawl. We will deploy the same software onto each node. The software can know about all the nodes. We have to minimize communication between machines and make sure each node does equal amount of work. How would your web crawler design change?

2. What if one node fails or does not work?
3. How do you know when the crawler is done?

```
>> Brute Force (DFS) Interview Prep

Python
# Brute Force Approach
class Solution:
    def crawl(self, startUrl, htmlParser):
        # Brute Force - DFS from every unvisited node
        visited = set()

#329 **HARD**
Longest Increasing Path in a Matrix
 LeetCode · SimplifyLust · WubCC · LeeCode · Editorial
 Array · DFS · BFS · Graph · Topological Sort · Memoization · Matrix
 Lints Grind 189

Problem:
 Given an $m \times n$ integers matrix, return the length of the longest increasing path in matrix.
 From each cell, you can either move in four directions: left, right, up, or down. You may not move diagonally or move outside the boundary (i.e., wrap-around is not allowed).

Example 1:

9	9	4
6	6	8
2	1	1

Input: matrix = [[9,9,4],[6,6,8],[2,1,1]]
 Output: 4
 Explanation: The longest increasing path is [1, 2, 6, 9].

Example 2:

3	4	5
3	2	6
2	2	1

Input: matrix = [[3,4,5],[3,2,6],[2,2,1]]
 Output: 4
 Explanation: The longest increasing path is [3, 4, 5, 6]. Moving diagonally is not allowed.
 Example 3:
 Input: matrix = [[1]]
 Output: 1
 Constraints:
 • $m = \text{matrix.length}$
 • $n = \text{matrix[0].length}$
 • $1 \leq m, n \leq 200$
 • $0 \leq \text{matrix[i][j]} \leq 231 - 1$

DPS · BFS · Union Find · Graph
Little Danny Zhang

Problem:

In this problem, a rooted tree is a directed graph such that, there is exactly one node (the root) for which all other nodes are descendants of this node, plus every node has exactly one parent, except for the root node which has no parents.

The given input is a directed graph that started as a rooted tree with n nodes (with distinct values from 1 to n), with one additional directed edge added. The added edge has two different vertices chosen from 1 to n , and was not an edge that already existed.

The resulting graph is given as a 2D-array of edges. Each element of edges is a pair $[u, v]$ that represents a directed edge connecting nodes u and v , where u is a parent of child v .

Return an edge that can be removed so that the resulting graph is a rooted tree of n nodes. If there are multiple answers, return the answer that occurs last in the given 2D-array.

Example 1:

Input: edges = [[1,2],[1,3],[2,3]]
Output: [2,3]

Example 2:

DPS · LeetCode · By Pattern

— 2213 —

LeetCode

Input: edges = [[1,2],[2,3],[3,4],[4,1],[1,5]]
Output: [4,1]

Constraints:

- $n == \text{edges.length}$
- $3 \leq n \leq 1000$
- $\text{edges}[i].\text{length} == 2$
- $1 \leq u_i, v_i \leq n$
- $u_i \neq v_i$

Array · Hash Table · DFS · BFS

Like · Donny Zhang

Problem:

There is a 1 million by 1 million grid on an XY-plane, and the coordinates of each grid square are (x, y).

We start at the source = [sx, sy] square and want to reach the target = [tx, ty] square. There is also an array of blocked squares, where each blocked[i] = [xi, yi] represents a blocked square with coordinates (xi, yi).

Each move, we can walk one square north, east, south, or west if the square is not in the array of blocked squares. We are also not allowed to walk outside of the grid.

Return true if and only if it is possible to reach the target square from the source square through a sequence of valid moves.

Example 1:

Input: blocked = [[0,1],[1,0]], source = [0,0], target = [0,2]
Output: false

Explanation: The target square is inaccessible starting from the source square because we cannot move.

We cannot move north or east because those squares are blocked.

We cannot move south or west because we cannot go outside of the grid.

Example 2:

Input: blocked = [], source = [0,0], target = [99999,99999]
Output: true

Explanation: Because there are no blocked cells, it is possible to reach the target square.

Constraints:

- 0 <= blocked.length <= 200
- blocked[i].length == 2
- 0 <= xi, yi < 10⁶
- source.length == target.length == 2
- 0 <= sx, sy, tx, ty < 10⁶
- source != target
- It is guaranteed that source and target are not blocked.

#1192 **HARD** Critical Connections in a Network

LeetCode · [Simplest](#) · [Naive](#) · [LeeCode](#) · [Editorial](#)

DPS · Graph · [Biconnected Component](#)

List: Danny Zhang

Problem:

There are n servers numbered from 0 to $n - 1$ connected by undirected server-to-server connections forming a network where $connections[i] = [a, b]$ represents a connection between servers a and b . Any server can reach other servers directly or indirectly through the network.

A critical connection is a connection that, if removed, will make some servers unable to reach some other server.

Return all critical connections in the network in any order.

Example 1:

Input: $n = 4$, $connections = [[0, 1], [1, 2], [2, 0], [1, 3]]$
Output: $[[1, 3]]$
Explanation: $[[2, 1]]$ is also accepted.

Example 2:

Input: $n = 2$, $connections = [[0, 1]]$
Output: $[[0, 1]]$

Constraints:

- $2 \leq n \leq 105$
- $n - 1 \leq connections.length \leq 105$
- $0 \leq a_i, b_i \leq n - 1$
- $a_i \neq b_i$

- There are no repeated connections.

Quick Review — DFS 23 questions · insights · complexity · solution

#463 Island Perimeter [Easy]

Key Insights

- Each land cell contributes 4 edges if isolated.
- For every adjacent pair of land cells (neighbors horizontally or vertically), the shared edge should be subtracted from the total perimeter.
- Instead of DFS/BFS, we can iterate the grid and check the four neighbors for each land cell.
- Alternatively, one may use DFS/BFS to visit all connected cells if needed, but an iterative solution is straightforward with O(rows*cols) time complexity.

Space & Time

Time Complexity: $O(m \times n)$, where n is the number of rows and m is the number of columns.
Space Complexity: $O(1)$ for the iterative solution (excluding the input storage).

Solution

We iterate through every cell in the grid. For each land cell, we initially add 4 to the perimeter. Then we check its four neighbors (up, down, left, right). For every neighbor that is also land, we subtract 1 from the current cell's contribution since that side is not exposed. This simple approach ensures that shared borders between adjacent land cells are not over-counted.

#733 Flood Fill [Easy]

Key Insights

- The flood fill operation can be executed using either DFS (Depth First Search) or BFS (Breadth First Search).
- A check is needed at the beginning to determine if the new color is the same as the original; if so, no changes are needed.
- The algorithm recursively or iteratively visits each pixel that is directly adjacent and matches the original color, then updates its color.
- The problem has a worst-case scenario where all pixels are the same color, leading to a full traversal of the grid.

Space & Time

Time Complexity: $O(m \times n)$, where m and n are the dimensions of the image grid, because in the worst-case all cells are visited.
Space Complexity: $O(m \times n)$ in the worst-case due to the recursion stack (or BFS queue) if the entire image needs to be filled.

Solution

We use a DFS approach to perform the flood fill. The algorithm starts at the given starting pixel and uses recursion to fill connected pixels with the same original color. The following steps are key:

- Check if the starting pixel's color is already the target color. If so, return the image immediately.
- Define a recursive helper function that: Checks boundary conditions. Updates the current pixel's color. Recursively calls itself on the four adjacent directions (up, down, left, right).
- Return the modified image after the recursion completes.

Data structures used:

- Recursion call stack for the DFS implementation.
- Variables to store the image dimensions and original color.

#130 Surrounded Regions [Medium]

Key Insights

- Regions connected to the border are not captured.
- Use DFS/BFS from border 'O's to mark safe cells.
- After marking, flip all remaining 'O's to 'X' and then revert the marked cells back to 'O'.

DFS · LeeMastery — By Pattern

— 2248 —

LeeMastery

Space & Time

Time Complexity: $O(m \times n)$
Space Complexity: $O(m \times n)$ in the worst case due to recursion stack or queue storage for DFS/BFS

Solution

The solution involves two main steps. First, traverse the board's borders and run a DFS or BFS from any encountered 'O', marking it (e.g., using '-') to indicate that it should not be flipped. Next, go through each cell in the board; flip any remaining 'O' (i.e., not marked safe) to 'X' and change the temporary marker '-' back to 'O'. This approach ensures only the regions completely surrounded by 'X' are captured.

#133 Clone Graph [Medium]

Key Insights

- The graph is undirected and connected.
- Each node must be cloned exactly once to prevent cycles and repetitions.
- Use a mapping/dictionary to keep track of cloned nodes.
- A depth-first search (DFS) or breadth-first search (BFS) can be used to traverse and clone the graph.
- Handle edge cases where the graph might be empty.

Space & Time

Time Complexity: $O(N + E)$, where N is the number of nodes and E is the number of edges, because each node and each edge are traversed once.
Space Complexity: $O(N)$, to store the mapping from original nodes to their clones, and for the recursion/queue used in traversal.

Solution

We employ a depth-first search (DFS) approach to clone the graph. The main idea is to create a mapping (hash table) that links each original node to its corresponding cloned node. During the DFS traversal, if a node is encountered for the first time, a new node is created and stored in the mapping; then, the algorithm recursively clones all of its neighbors. For an already visited node, the cloned node is directly returned from the mapping. This ensures that every node is cloned only once and correctly handles cycles in the graph.

#200 Number of Islands [Medium]

Key Insights

- Use graph traversal (DFS/BFS) to explore connected components of land.
- Iterate over the matrix and start a traversal (e.g., DFS) when encountering an unvisited '1'.
- During traversal, mark visited cells to avoid duplicate counting.
- Each DFS/BFS call completely explores one island.
- Alternative approach can use Union-Find to group connected lands.

Space & Time

Time Complexity: $O(m \times n)$, as each cell is visited at most once.
Space Complexity: $O(m \times n)$ in the worst-case scenario due to recursion stack (DFS) or auxiliary data structures.

Solution

We solve the problem using a DFS-based approach. The algorithm iterates over each cell in the grid; when a '1' (land) is encountered, the DFS is initiated to mark the entire island (all connected '1's) as visited (by setting them to '0'). This prevents recounting the same island. The island count is incremented each time a new island is discovered and fully explored.

#207 Course Schedule [Medium]

Key Insights

- This problem can be modeled as a directed graph where courses are nodes and prerequisites are edges.
- If the graph has a cycle, then it is not possible to complete all courses.

DFS · LeeMastery — By Pattern

— 2249 —

LeeMastery

- We can detect cycles using either Topological Sort (BFS/Kahn's algorithm) or DFS-based cycle detection.
- The time complexity is $O(V + E)$, where V is the number of courses and E is the number of prerequisite pairs.

Space & Time

Time Complexity: $O(V + E)$
Space Complexity: $O(V + E)$

Solution

We solve the problem using the Topological Sort algorithm (BFS/Kahn's algorithm). First, we build a graph (using an adjacency list) and track the indegree (number of prerequisites) for each course. We then find all courses with an indegree of zero (courses with no prerequisites) and add them to a processing queue. While the queue is not empty, we remove a course from the queue, reduce the indegree for its neighboring courses, and if any neighbor's indegree becomes zero, we add it to the queue as well. If we successfully process all courses, then it means that the graph was acyclic and a valid schedule exists, returning true. If not, a cycle exists, and we return false.

#210 Course Schedule II [Medium]

Key Insights

- This is a topological sort problem on a directed graph.
- The courses are nodes, and prerequisites form directed edges.
- We can solve the problem by either:
- Using DFS with cycle detection and a stack for topological ordering.
- Using BFS (Kahn's Algorithm) to process nodes with zero in-degrees.
- If at any point no node with a zero in-degree is available, a cycle exists and no valid order can be produced.

Space & Time

Time Complexity: $O(V + E)$ where V is the number of courses and E is the number of prerequisite pairs.
Space Complexity: $O(V + E)$ for storing the graph and in-degree array.

Solution

We treat the problem as a topological sort on a directed acyclic graph (DAG). For a BFS approach using Kahn's algorithm:

- Build an adjacency list for the graph and an in-degree array to record the number of prerequisites (incoming edges) for each course.
- Initialize a queue with all courses that have an in-degree of zero (i.e., courses that can be taken without prerequisites).
- Dequeue nodes from the queue, add them to the ordering, and reduce the in-degree of their neighbors.
- If a neighbor's in-degree becomes zero, add it to the queue.
- If the final ordering includes all courses, return the ordering; otherwise, return an empty array indicating a cycle. The chosen data structures are:

- A list (or array) for the in-degree counts.
- A dictionary (or array of lists) for the adjacency list.
- A queue to process nodes with zero in-degree.

#261 Graph Valid Tree [Medium]

Key Insights

- A tree must be acyclic and connected.
- For n nodes, a valid tree must have exactly $n - 1$ edges.
- A DFS/BFS traversal can check connectivity and simultaneously detect cycles.
- The Union-Find (disjoint set) approach provides an alternative for cycle detection and connectivity verification.

Space & Time

Time Complexity: $O(n + e)$, where e is the number of edges
Space Complexity: $O(n + e)$ for storing the graph and traversal/union-find structures

Solution

We can solve the problem using either a DFS/BFS approach or a Union-Find algorithm. For the DFS/BFS method, we first check if the number of edges is exactly $n - 1$. If not, it cannot be a tree. Then, we build an adjacency list for the

DFS · LeeMastery — By Pattern

— 2250 —

LeeMastery

graph and perform a DFS starting from node 0 while keeping track of visited nodes and parent information to avoid false-positive cycle detection. If during DFS we encounter a node that has been visited (and is not the parent), then a cycle exists. Finally, if all nodes are reached from node 0 and no cycle is found, the graph is a valid tree. Using Union-Find, we iterate over each edge and try to union the two nodes. If they already share the same parent (i.e., are in the same set), a cycle exists. After processing all edges, we confirm that exactly one connected component exists.

#310 Minimum Height Trees [Medium]

Key Insights

- A tree can have at most two centers that will serve as the roots for its minimum height trees.
- Instead of trying all possible roots, we can remove leaves layer by layer until we are left with the central node(s).
- The process is similar to a topological sort on the tree.
- When there are 2 or fewer nodes left, these nodes are the centers (roots) of MHTs.

Space & Time

Time Complexity: $O(n)$ where n is the number of nodes, since we process each node and edge once.
Space Complexity: $O(n)$ for storing the graph and additional data structures like the leaves list.

Solution

The solution builds an undirected graph from the input, then identifies and removes node-leaves iteratively. A leaf is defined as a node connected to only one other node. By repeatedly removing the leaves and updating the graph (decreasing neighbor degrees), the algorithm peels away the outer layers of the tree. When only one or two nodes remain, these nodes are the centers of the tree and form the roots of the minimum height trees.

#323 Number of Connected Components in an Undirected Graph [Medium]

Key Insights

- Use an adjacency list to represent the graph.
- A DFS (or BFS) traversal from an unvisited node will traverse an entire connected component.
- Each new DFS/BFS call from an unvisited node signals a separate connected component.
- Alternatively, the Union-Find data structure can be used to union connected nodes and count distinct sets.

Space & Time

Time Complexity: $O(n + e)$, where n is the number of nodes and e is the number of edges.
Space Complexity: $O(n + e)$ due to the storage of the graph and tracking of visited nodes.

Solution

We solve the problem by iterating over each node and performing a DFS for any node that hasn't been visited. The DFS uses an iterative approach with a stack to traverse all nodes in a connected component. Each DFS initiation corresponds to one connected component. This method efficiently explores the graph using an adjacency list and marks nodes as visited to prevent redundant traversals.

#417 Pacific Atlantic Water Flow [Medium]

Key Insights

- Reverse the typical DFS/BFS perspective: start from the oceans and work inward.
- Maintain two matrices (or sets) to keep track of cells reachable from the Pacific and Atlantic edges.
- A cell can be added to the result if it is reached in both traversals.
- The height constraint ensures water flows only in non-increasing order.

Space & Time

Time Complexity: $O(m * n)$ where m is the number of rows and n is the number of columns. Each cell is processed up to twice (once from each ocean).
Space Complexity: $O(m * n)$ for the visited matrices and the recursion/queue used in DFS/BFS.

Solution

DFS · LeeMastery — By Pattern

— 2251 —

LeeMastery

The solution uses depth-first search (DFS) from the ocean boundaries. We initialize two boolean matrices, one for each ocean. For the Pacific, we start DFS from the leftmost column and top row; for the Atlantic, we start from the rightmost column and bottom row. In each DFS, if the next cell has a height equal to or greater than the current cell and hasn't been visited, we continue the search. Finally, we scan through the grid to collect cells that are reachable from both oceans. This reverse search simplifies the path validations and leverages the allowed water flow conditions.

#490 The Maze [Medium]

Key Insights

- The ball continues moving in one direction until it hits a wall (or the boundary, which is considered a wall).
- You must simulate the ball's rolling rather than taking a single step.
- Even if the ball passes through the destination, it is only valid if it can stop exactly there.
- A breadth-first search (BFS) or depth-first search (DFS) strategy is ideal because we need to explore all stopping positions.
- Use a visited structure to avoid revisiting positions and thus prevent infinite loops.

Space & Time

Time Complexity: $O(m * n)$ where m and n are the dimensions of the maze.
Space Complexity: $O(m * n)$ due to the storage used by the visited matrix and the BFS/DFS queue or recursion stack.

Solution

We simulate the ball's movement using a breadth-first search (BFS) approach. Each time we pick a stop position, we try to roll in all four directions until the ball hits a wall. At that point, if the new stopping position has not been visited, we mark it as visited and add it to our queue. If we ever reach the destination exactly, we return true. The key is simulating the "roll" by iteratively moving in a direction until no further move is possible.

We store the coordinates in a queue (or stack for DFS) along with a 2D visited array to monitor which positions have been processed. The directions are maintained in a list/array, and for each direction, we keep moving until the next cell would be out of bounds or a wall.

#694 Number of Distinct Islands [Medium]

Key Insights

- Use DFS/BFS to traverse and mark each island.
- For each island, record its shape relative to a starting coordinate to allow translation invariance.
- Represent the island's shape as a unique signature (e.g., tuple or string of relative positions).
- Use a set (or hash table) to store unique shapes.

Space & Time

Time Complexity: $O(m * n)$ as each cell is visited once.
Space Complexity: $O(m * n)$ in the worst-case due to recursion stack and storing island shapes.

Solution

Use depth-first search (DFS) to explore the grid. When an unvisited land cell (1) is encountered, initiate a DFS to traverse the entire island. Record each land cell's coordinates relative to the starting position of the island. This relative representation is invariant under translation, making it possible to compare island shapes. Store the canonical shape signature (for example, as a tuple or string) in a set to ensure uniqueness. Finally, return the size of the set as the number of distinct islands.

#695 Max Area of Island [Medium]

Key Insights

- Traverse each cell in the grid.
- Use Depth-First Search (DFS) or Breadth-First Search (BFS) to explore connected 1's.
- Mark visited cells to prevent double counting (e.g., by setting them to 0).

DFS · LeeMastery — By Pattern

— 2252 —

LeeMastery

- Maintain and update a maximum area count during traversal.
- The grid's boundaries are naturally water, so no extra edge processing is needed.

Space & Time

Time Complexity: $O(m * n)$ where m and n are the dimensions of the grid since every cell is visited at most once.
Space Complexity: $O(m * n)$ in the worst-case scenario for the recursion stack (or auxiliary data structures) when the grid is entirely land.

Solution

The solution leverages a DFS approach to iterate over each cell in the given grid. When a cell with a value of 1 is encountered, a DFS is initiated from that cell to calculate the area of the island connected to it. Cells are marked as visited (by changing them from 1 to 0) during the DFS to avoid revisiting. The DFS explores all four directions (up, down, left, right) and accumulates the count of connected cells. The maximum area found among all islands is returned at the end. This approach efficiently computes the largest island area with a simple traversal mechanism.

#721 Accounts Merge [Medium]

Key Insights

- Two accounts are merged if they share at least one common email.
- Treat each email as a node in a graph; accounts represent connected components.
- Both DFS/BFS and Union-Find can be used to find connected components.
- Keep a mapping from email to name because all emails in a connected component belong to the same person.
- After grouping, sort the emails and prepend the name to form the final account list.

Space & Time

Time Complexity: $O(N * M * \log M)$ where N is the number of accounts and M is the number of emails per account (owing to sorting and union operations).
Space Complexity: $O(N * M)$, used for storing email mappings and union-find structures.

Solution

The solution involves using a Union-Find (Disjoint Set Union) data structure to merge emails that are connected by being on the same account. For each account, we union the first email with every other email in that account. We also maintain a mapping from email to owner name. After processing all accounts, we group the emails by their root parent derived from the union-find structure. For each group, we sort the emails and prepend the owner's name. Finally, we return the merged list of accounts.

#785 Is Graph Bipartite? [Medium]

Key Insights

- A graph is bipartite if you can assign two colors to each node such that no two adjacent nodes share the same color.
- The challenge may require exploring disconnected components.
- BFS or DFS can be used to attempt the two-coloring, and a conflict during coloring indicates the graph is not bipartite.
- Union Find is an alternative approach, but BFS/DFS is more intuitive for graph coloring problems.

Space & Time

Time Complexity: $O(V + E)$ where V is the number of nodes and E is the number of edges, since every node and edge is traversed at most once.
Space Complexity: $O(V)$, for the color array and the queue (or recursion stack) used in BFS (or DFS).

Solution

We use a BFS/DFS approach to assign colors (0 and 1) to nodes. A color array, initially set to -1 for all nodes, is maintained. For each unvisited node (color = -1), we start a BFS (or DFS) and assign it an initial color (e.g., 0). For every visited neighbor, if it has not been colored, assign it the opposite color; if it is already colored with the same color as the current node, a conflict has occurred, and the graph is not bipartite. This method gracefully handles

DFS · LeeMastery — By Pattern

— 2253 —

LeeMastery

disconnected components by iterating over all nodes.

#1230 Web Crawler [Medium]

Key Insights

- Treat the set of webpages as a graph where each URL is a node and an edge exists from one URL to another if it is returned by `HtmlParser.getUrls()`.
- Use either breadth-first search (BFS) or depth-first search (DFS) to traverse the webpages.
- Extract the hostname from a URL to ensure that only URLs on the same domain are crawled.
- Maintain a visited set (or equivalent) to avoid processing the same URL multiple times.

Space & Time

Time Complexity: $O(N * E)$ where N is the number of nodes (URLs) and E is the number of edges (links between URLs) encountered during the crawl.
Space Complexity: $O(N)$ for storing the visited URLs and the queue/stack used for traversal.

Solution

The solution uses a BFS (or DFS) approach to traverse the web graph:
- Extract the hostname from `startUrl` (for instance, by splitting on `"/"` and then the first `"/"` that follows). - Initialize a visited set to keep track of URLs that have been crawled. - Use a queue to implement the BFS. Enqueue the `startUrl`. - While the queue is not empty, dequeue a URL and retrieve its outgoing links using `HtmlParser.getUrls()`. - For each URL obtained, extract its hostname and compare it with the hostname of `startUrl`. If it matches and it has not been visited before, add it to the visited set and enqueue it. - Finally, return the set of visited URLs.
This approach guarantees that each URL is processed only once and that only URLs from the same hostname are crawled.

#1242 Web Crawler Multithreaded [Medium]

Key Insights

- Use multiple threads to perform concurrent crawling, which speeds up the process over a single-threaded approach.
- Maintain a thread-safe set (visited) to ensure no URL is processed twice.
- Utilize a work queue to manage URLs pending processing.
- Filter URLs based on the hostname extracted from `startUrl`.
- Apply synchronization (locks or concurrent data structures) to avoid race conditions when multiple threads access shared data.

Space & Time

Time Complexity: $O(N)$ where N is the number of URLs processed, with additional constant factors due to threading overhead.
Space Complexity: $O(N)$ for storing the visited URLs and the work queue.

Solution

The solution initializes a shared work queue with the `startUrl` and a thread-safe visited set. Each worker thread dequeues a URL, retrieves its linked URLs via the blocking `HtmlParser.getUrls()` call, and filters the resulting URLs by comparing their hostnames with the start URL's hostname. New URLs that have not yet been visited are added to both the visited set and the work queue. The use of a thread pool or multiple worker threads along with synchronization ensures that the crawler processes URLs concurrently while avoiding race conditions. The approach follows a BFS-like pattern spread across multiple threads.

#269 Alien Dictionary [Hard]

Key Insights

- Build a graph where each unique character is a node.
- Compare adjacent words to determine the first different character, which gives the ordering (directed edge).

DFS · LeeMastery — By Pattern

— 2254 —

LeeMastery

- Ensure all characters, even those without edges, are represented.
- Use a topological sort (using DFS or BFS) to determine a valid character ordering.
- Handle edge cases, such as words where a longer word appears before its prefix which is invalid.

Space & Time

Time Complexity: $O(N * L + V + E)$ where N is the number of words, L is the average length of each word, V is the number of unique characters, and E is the number of edges derived from adjacent word comparisons.
Space Complexity: $O(V + E)$ for storing the graph and additional data structures for topological sorting.

Solution

We use a graph-based approach to solve the problem. First, we initialize a graph (adjacency list) and in-degree dictionary for all unique characters. We then iterate through each pair of consecutive words, comparing them character by character to find the first pair that differs. This difference implies an order: the first character should come before the second character. We add a directed edge accordingly and update the in-degree for the target character.

To get the final ordering, we perform a topological sort using Kahn's algorithm:
- Enqueue characters with in-degree zero. - Remove characters from the queue and append them to our result. - Decrement the in-degree of neighboring nodes. - If a neighbor's in-degree becomes zero, enqueue it. If the result's length equals the number of unique nodes, we have a valid ordering; otherwise, a cycle exists, and we return an empty string.

#329 Longest Increasing Path in a Matrix [Hard]

Key Insights

- The problem can be modeled as a graph where each cell is a node connected to its neighbors if the neighbor's value is greater.
- A Depth First Search (DFS) with memoization is effective to avoid recalculations.
- Dynamic Programming (DP) is used to cache the longest path found from each cell.
- Since each cell can be a start point, compute DFS for every cell and update the global maximum.

Space & Time

Time Complexity: $O(m * n)$ - each cell is computed once due to memoization.
Space Complexity: $O(m * n)$ - space is used for the memoization cache and recursion stack.

Solution

We solve the problem using a DFS approach combined with memoization to keep track of already computed longest paths from each cell. For each cell in the matrix, a DFS is initiated to explore all four valid directions (up, down, left, right). If a neighboring cell has a larger value, the DFS recurses from that neighbor. The result for each cell is cached in a 2D memoization table, ensuring that each cell is processed only once. After processing all cells, the maximum value in the memo table represents the longest increasing path in the entire matrix.

#685 Redundant Connection II [Hard]

Key Insights

- The extra edge introduces one of two issues:
 - A node has two parents.
 - A cycle exists in the graph.
- First, scan through edges to detect if any node gets two parents. If found, there are two candidate edges.
- Use the Union-Find data structure (Disjoint Set Union) to detect cycles.
- Depending on whether a conflict (two parents) exists and/or a cycle is detected, decide which edge to remove:
- If a node has two parents, test by ignoring the second candidate edge during union-find. If no cycle forms, the second candidate is removable; otherwise, remove the first candidate.
- If no conflict exists, simply remove the edge that causes a cycle.

DFS · LeeMastery — By Pattern

— 2255 —

LeeMastery

Space & Time

Time Complexity: $O(n)$
Space Complexity: $O(n)$

Solution

The solution consists of two main steps:
- Traverse the list of edges to detect whether any node has two parents. If such a node is found, mark the two candidate edges (candidate1: the earlier edge, candidate2: the later edge). - Use the Union-Find algorithm to iterate over the edges: If there is a conflict (i.e., a node with two parents), skip candidate1 initially. While processing edges with Union-Find, check if adding an edge would create a cycle. Finally, based on the presence of a cycle and the two-parent conflict, decide which candidate edge to return.

Key Data Structures:

- An array (or hash map) to track the parent of each node. - The Union-Find (Disjoint Set Union) structure to union sets and detect cycles.

#1030 Escape a Large Maze [Hard]

Key Insights

- The maximum number of blocked cells is 200, which limits the size of a potential completely enclosed region.
- Even if the target is unreachable by direct search, if the BFS (or DFS) explores more than a calculated threshold (based on the blocked cells count), then the region is not fully enclosed.
- Perform two BFS explorations: one starting from the source and one from the target. If neither search is trapped within a small region, then an escape path exists.
- Early exit in BFS if the target is reached or if the number of visited nodes exceeds the maximum possible enclosed area.

Space & Time

Time Complexity: $O(B^2)$ in the worst case, where B is the number of blocked cells (with $B \leq 200$).
Space Complexity: $O(B^2)$ due to the storage of visited cells in the worst-case scenario.

Solution

The solution uses the Breadth-First Search (BFS) algorithm. A key observation here is that the blocked cells can only enclose a limited area. We compute a threshold (maxSteps) based on the number of blocked cells ($n(n-1)/2$) to determine if the search is confined. The BFS from the source (and similarly from the target) stops in two cases: if the target is reached or if the visited area exceeds the threshold, indicating that the region is not fully enclosed by blocked cells. Running BFS from both the source and target ensures that neither is trapped inside a small bounded region.

#1192 Critical Connections in a Network [Hard]

Key Insights

- The problem is about identifying bridges in an undirected graph.
- Use Depth-First Search (DFS) to explore the graph.
- During DFS, track discovery times and low-link values for each node.
- For an edge (u, v) , if $\text{low}[v] > \text{disc}[u]$ then (u, v) is a critical connection.
- Tarjan's algorithm is well-suited for solving this problem in $O(n + m)$ time.

Space & Time

Time Complexity: $O(n + m)$ where n is the number of nodes and m is the number of connections.
Space Complexity: $O(n + m)$ for the graph representation and DFS recursion stack.

Solution

We solve this problem using DFS-based approach (Tarjan's algorithm). First, we transform the list of connections into an adjacency list for efficient graph traversal. We then start a DFS from an arbitrary node (node 0, since the graph is connected) while maintaining two arrays: one for discovery times (disc) and one for low-link values (low).

DFS · LeeMastery — By Pattern

— 2256 —

LeeMastery

The discovery time is the time when the node is first visited, and the low-link value is the smallest discovery time that can be reached from that node (including via back edges). For each edge (u, v) , after a DFS call on v , if $\text{low}(v) > \text{disc}(u)$ then the edge (u, v) is a bridge because v (and its descendants) cannot reach u or any of its ancestors without this edge. This edge is then recorded as a critical connection.

Array · Binary Search

List: Denny Zhang

Problem:

Given a sorted array of distinct integers and a target value, return the index if the target is found. If not, return the index where it would be if it were inserted in order.

You must write an algorithm with $O(\log n)$ runtime complexity.

Example 1:

Input: nums = [1,3,5,6], target = 5

Output: 2

Example 2:

Input: nums = [1,3,5,6], target = 2

Output: 1

Example 3:

Input: nums = [1,3,5,6], target = 7

Output: 4

Constraints:

- $1 \leq \text{nums.length} \leq 104$
- $-104 \leq \text{nums}[i] \leq 104$
- nums contains distinct values sorted in ascending order.
- $-104 \leq \text{target} \leq 104$

Python

```
# Brute Force Approach
class Solution:
    def searchInsert(self, nums, target):
        # Brute Force O(n) - Linear time instead of binary search
        for i, val in enumerate(nums):
            if val == target:
                return i
        return -1
```

Python

Python

```
# Python solution using binary search
def searchInsert(nums, target):
    # Initialize low and high pointers for binary search
    low, high = 0, len(nums) - 1
    # Return binary search until low pointer exceeds high pointer
    while low <= high:
        mid = (low + high) // 2 # Calculate the middle index
        if nums[mid] == target:
            return mid # Return mid if target is found
        elif target < nums[mid]:
            high = mid - 1 # Narrow search on the left side
        else:
            low = mid + 1 # Narrow search on the right side
    # Return low pointer as the insertion index when target is not found
    return low
```

```
# Example usage
print(searchInsert([1, 3, 5, 6], 5)) # Output: 2
```

Python

```

[+] Binary Search — Pattern Solution (matched from community answers)

Python

# Binary search solution to find the integer square root
def mySqrt(x):
    # Edge case for small numbers
    if x <= 1:
        return x

    low, high = 0, x
    ans = 0
    # Binary search loop
    while low <= high:
        mid = (low + high) // 2
        # If mid squared equals x, we found the exact square root
        if mid * mid == x:
            return mid
        # If mid squared is less than x, store mid and search right half
        elif mid * mid < x:
            ans = mid # candidate answer
            low = mid + 1
        else:
            # If mid squared is more than x, search left half
            high = mid - 1
    return ans

# Example usage:
print(mySqrt(4)) # Output: 2
print(mySqrt(8)) # Output: 2
```

Lists Grid 169

Problem:

You are a product manager and currently leading a team to develop a new product. Unfortunately, the latest version of your product fails the quality check. Since each version is developed based on the previous version, all the versions after a bad version are also bad.

Suppose you have n versions $[1, 2, \dots, n]$ and you want to find out the first bad one, which causes all the following ones to be bad.

You are given an API `bool isBadVersion(version)` which returns whether version is bad. Implement a function to find the first bad version. You should minimize the number of calls to the API.

Example 1:

Input: $n = 5$, `bad = 4`
Output: 4
Explanation:
call `isBadVersion(3)` -> false
call `isBadVersion(5)` -> true
call `isBadVersion(4)` -> true
Then 4 is the first bad version.

Example 2:

Input: $n = 1$, `bad = 1`
Output: 1
Constraints:

- $1 \leq \text{bad} \leq n \leq 2^{31} - 1$

```
Python

# Python implementation of First Bad Version
class Solution:
    def firstBadVersion(self, n: int) -> int:
        # Initialize left and right pointers to the first version and right pointer to the last version
        left, right = 1, n
        while left < right:
            # Calculate the mid point to avoid potential overflow
            mid = (left + right) // 2
            # Call the API isBadVersion to check if mid version is bad
            if isBadVersion(mid):
                # If mid is bad, search the left half including mid
                right = mid
            else:
                # If mid is not bad, search the right half excluding mid
                left = mid + 1
        # Since left equals right, we found the first bad version
        return left

Python
```

```
class Solution {
    def firstBadVersion(self, n: int) -> int:
        l = 1
        r = n

        while l < r:
            m = (l + r) >> 1
            if isBadVersion(m):
                r = m

Guess Number Higher or Lower

LeetCode · Simplest · WalkCC · LeetCode · Editorial

Math · Binary Search · Interactive

Link: Dong Zhang

Problem:

We are playing the Guess Game. The game is as follows:

I pick a number from 1 to n. You have to guess which number I picked (the number I picked stays the same throughout the game).

Every time you guess wrong, I will tell you whether the number I picked is higher or lower than your guess.

You call a pre-defined API int guess(num), which returns three possible results:

- 1: Your guess is higher than the number I picked (i.e. num > pick).
- 1: Your guess is lower than the number I picked (i.e. num < pick).
- 0: Your guess is equal to the number I picked (i.e. num == pick).

Return the number that I picked.

Example 1:

Input: n = 10, pick = 6

Output: 6

Example 2:

Input: n = 1, pick = 1

Output: 1

Example 3:

Input: n = 2, pick = 1

Output: 1

Constraints:

```
• 1 <= n <= 231 - 1
• 1 <= pick <= n
```

Python

```
Python
class Solution:
    def guessNumber(self, n: int) -> int:
        # Initialize low and high pointers
        low, high = 1, n
        # Continue binary search until low exceeds high
        while low <= high:
            # Calculate mid point safely to prevent overflow
            mid = low + (high - low) // 2
            # Call the guess API with mid
            result = guess(mid)
            # If the guess is correct, return mid
            if result == 0:
                return mid
            # If guess was too high, adjust the high pointer
            elif result == -1:
                high = mid - 1
            # If guess was too low, adjust the low pointer
            else:
                low = mid + 1
        # Return low (ideally should never reach here if pick exists in [1, n])
        return low
```

Python

```
Python
# The guess API is already defined for you.
# @param num, your guess
# @return -1 if num is higher than the picked number
#         1 if num is lower than the picked number
#         0 if num is equal to the picked number
# def guess(num: int) -> int:

class Solution:
    def guessNumber(self, n: int) -> int:
        l = 1

EASY

Binary Search

LeetCode - SimplyEasy - WUCC - LeetCode - Editorial

Array - Binary Search

LeetCode 704

Problem:

Given an array of integers nums which is sorted in ascending order, and an integer target, write a function to search target in nums. If target exists, then return its index. Otherwise, return -1.

You must write an algorithm with O(log n) runtime complexity.

Example 1:

Input: nums = [-1,0,3,5,9,12], target = 9

Output: 4

Explanation: 9 exists in nums and its index is 4

Example 2:

Input: nums = [-1,0,3,5,9,12], target = 2

Output: -1

Explanation: 2 does not exist in nums so return -1

Constraints:

• 1 <= nums.length <= 104

• -104 <= nums[i], target <= 104

• All the integers in nums are unique.

• nums is sorted in ascending order.

>> Brute Force [Binary Search] Interview Prep

```
Python

# Brute-force approach
class Solution:
    def search(self, nums: List[int], target: int) -> int:
        # Iterate over the array, ignoring sorted property
        for i, val in enumerate(nums):
            if val == target:
                return i
        return -1
```

Python

Python code for binary search.

```
def search(nums, target):
    # Set initial boundaries for the search
    left, right = 0, len(nums) - 1
    # Loop until the search space is empty
    while left <= right:
        # Calculate middle index to avoid overflow
        mid = left + (right - left) // 2
        # Check if the mid element matches the target
        if nums[mid] == target:
            return mid
        # If target is smaller than mid element, narrow search to left half
        elif target < nums[mid]:
            right = mid - 1
        # Else, narrow search to right half
        else:
            left = mid + 1
    # Target not found, return -1
    return -1
```

```
# Example usage:
print(search([-1,0,3,5,9,12], 9)) # Expected output: 4
```

Python

```
class Solution:

[*] Binary Search — Pattern Solution (matched from community answers)

Python

```

# Python code for binary search

def search(nums, target):
    # Set initial boundaries for the search
    left, right = 0, len(nums) - 1

    # Loop until the search space is empty
    while left <= right:
        # Calculate middle index to avoid overflow
        mid = left + (right - left) // 2

        # Check if the mid element matches the target
        if nums[mid] == target:
            return mid

        # If target is smaller than mid element, narrow search to left half
        elif target < nums[mid]:
            right = mid - 1

        # Else, narrow search to right half
        else:
            left = mid + 1

    # Target not found, return -1
    return -1

# Example usage:
print(search([-1, 0, 3, 5, 9, 12], 9)) # Expected output: 4

Search in Rotated Sorted Array

LeetCode - SimplifyLeetCode - WubCC - LeetCode - Editorial

Array - Binary Search

Lists Grid 169

Problem:

There is an integer array `nums` sorted in ascending order (with distinct values).

Prior to being passed to your function, `nums` is possibly left rotated at an unknown index `k` ($0 \leq k < \text{nums.length}$) such that the resulting array is `[nums[k], nums[k+1], ..., nums[n-1], nums[0], nums[1], ..., nums[k-1]]` (0-indexed). For example, `[0,1,2,4,5,6,7]` might be left rotated by 3 indices and become `[4,5,6,7,0,1,2]`.

Given the array `nums` after the possible rotation and an integer `target`, return the index of `target` if it is in `nums`, or `-1` if it is not in `nums`.

You must write an algorithm with $O(\log n)$ runtime complexity.

Example 1:

Input: `nums = [4,5,6,7,0,1,2]`, `target = 0`

Output: `4`

Example 2:

Input: `nums = [4,5,6,7,0,1,2]`, `target = 3`

Output: `-1`

Example 3:

Input: `nums = [1]`, `target = 0`

Output: `-1`

Constraints:

- $1 \leq \text{nums.length} \leq 5000$
- $-104 \leq \text{nums}[i] \leq 104$
- All values of `nums` are unique.
- `nums` is an ascending array that is possibly rotated.
- $-104 \leq \text{target} \leq 104$

[1] Binary Search — Pattern Solution (matched from community answers)

```
Python
# Define a function to search for the target in a rotated sorted array.
def search(nums, target):
    # Initialize pointers for binary search.
    left, right = 0, len(nums) - 1

    # Loop until the search space is exhausted.
    while left <= right:
        # Compute the middle index.
        mid = (left + right) // 2

        # If the mid element is the target, return its index.
        if nums[mid] == target:
            return mid

        # Check if the left part of the array is sorted.
        if nums[left] <= nums[mid]:
            # If the target is within the sorted left half, adjust the right pointer.
            if nums[left] <= target <= nums[mid]:
                right = mid - 1
            else:
                # Otherwise, search the right half.
                left = mid + 1
        else:
            # The right half must be sorted.
            if nums[mid] < target <= nums[right]:
                left = mid + 1
            else:
                right = mid - 1

    # If the target is not found, return -1.
    return -1

# Example usage:
# nums = [4, 5, 6, 7, 8, 9, 1, 2], target = 8
# print(search(nums, target)) # Expected output: 4
```

Find First and Last Position of Element in Sorted Array

LeetCode • SimplexLive • WubliCC • LeetCode • Editorial

Array • Binary Search
Like Denny Zhang

Problem:

Given an array of integers `nums` sorted in non-decreasing order, find the starting and ending position of a given target value.

If target is not found in the array, return `[-1, -1]`.

You must write an algorithm with $O(\log n)$ runtime complexity.

Example 1:

Binary Search • LeetCode — By Pattern

— 2305 —

LeetCode

```
def searchRange(nums, target):
    # Helper function to find the boundary index (leftmost or rightmost) for target.
    def findBoundary(left):
        left, right = 0, len(nums) - 1
        boundary = -1
        while left <= right:
            mid = (left + right) // 2
            # If the target is found, update boundary and continue to search on one side.
            if nums[mid] == target:
                boundary = mid
                if left == mid:
                    right = mid - 1 # Continue search on left half
                else:
                    left = mid + 1 # Continue search on right half
            elif nums[mid] < target:
                left = mid + 1
            else:
                right = mid - 1
        return boundary

    # Find the leftmost index
    leftIndex = findBoundary(True)
    if leftIndex == -1:
        return [-1, -1]
    # Find the rightmost index
    rightIndex = findBoundary(False)
    return [leftIndex, rightIndex]

# Example usage:
# nums = [5, 7, 7, 8, 8, 10]
# target = 8
# print(searchRange(nums, target)) # Output: [3, 4]
```

Python

```
class Solution:
    def searchRange(self, nums: List[int], target: int) -> List[int]:
        l, r = 0, len(nums) - 1
        while l <= r:
            mid = (l + r) // 2
            if nums[mid] == target:
                return [l, r]
            elif nums[mid] < target:
                l = mid + 1
            else:
                r = mid - 1
        return [-1, -1]

# Example usage:
# nums = [5, 7, 7, 8, 8, 10]
# target = 8
# print(searchRange(nums, target)) # Output: [3, 4]
```

Binary Search • LeetCode — By Pattern

— 2309 —

LeetCode

Input: nums = [5, 7, 7, 8, 8, 10], target = 8

Output: [3, 4]

Example 2:

Input: nums = [5, 7, 7, 8, 8, 10], target = 6

Output: [-1, -1]

Example 3:

Input: nums = [], target = 0

Output: [-1, -1]

Constraints:

- $0 \leq \text{nums.length} \leq 105$
- $-109 \leq \text{nums}[i] \leq 109$
- `nums` is a non-decreasing array.
- $-109 \leq \text{target} \leq 109$

Find Minimum in Rotated Sorted Array

LeetCode · Simple · WalkCC · LeetCode · Editorial

Array · Binary Search
Lists Grid 169

Problem:

Suppose an array of length n sorted in ascending order is rotated between 1 and n times. For example, the array $nums = [0,1,2,4,5,6,7]$ might become:

- $[4,5,6,7,0,1,2]$ if it was rotated 4 times.
- $[0,1,2,4,5,6,7]$ if it was rotated 7 times.

Notice that rotating an array $[a[0], a[1], a[2], \dots, a[n-1]]$ 1 time results in the array $[a[n-1], a[0], a[1], a[2], \dots, a[n-2]]$.

Given the sorted rotated array $nums$ of unique elements, return the minimum element of this array. You must write an algorithm that runs in $O(\log n)$ time.

Example 1:

Input: $nums = [3,4,5,1,2]$
Output: 1
Explanation: The original array was $[1,2,3,4,5]$ rotated 3 times.

Example 2:

Input: $nums = [4,5,6,7,0,1,2]$
Output: 0
Explanation: The original array was $[0,1,2,4,5,6,7]$ and it was rotated 4 times.

Example 3:

Input: $nums = [11,13,15,17]$
Output: 11
Explanation: The original array was $[11,13,15,17]$ and it was rotated 4 times.

Constraints:

- $n == nums.length$
- $1 \leq n \leq 5000$
- $-5000 \leq nums[i] \leq 5000$
- All the integers of $nums$ are unique.
- $nums$ is sorted and rotated between 1 and n times.

MEDIUM

Longest Increasing Subsequence

LeetCode · Simplest · Rust · LeetCode · Editorial

Array · Binary Search · Dynamic Programming

Lists · Grid · 169

Problem:

Given an integer array `nums`, return the length of the longest strictly increasing subsequence.

Example 1:

Input: `nums = [10,9,2,5,3,7,10,18]`

Output: 4

Explanation: The longest increasing subsequence is `[2,3,7,10]`, therefore the length is 4.

Example 2:

Input: `nums = [0,1,0,3,2,3]`

Output: 4

Example 3:

Input: `nums = [7,7,7,7,7,7]`

Output: 1

Constraints:

`1 <= nums.length <= 2500`

`-104 <= nums[i] <= 104`

Follow up: Can you come up with an algorithm that runs in $O(n \log(n))$ time complexity?

[Math](#) · [Binary Search](#) · [Prefix Sum](#) · [Randomized](#)
[List](#) · [Grid](#) · [100](#)
Problem:

Binary Search · LeetCode · By Pattern — 2353 — LeetCode

You are given a 0-indexed array of positive integers w where $w[i]$ describes the weight of the i th index.

You need to implement the function `pickIndex()`, which randomly picks an index in the range $[0, w.length - 1]$ (inclusive) and returns it. The probability of picking an index i is $w[i] / \text{sum}(w)$.

For example, if $w = [1, 3]$, the probability of picking index 0 is $1 / (1 + 3) = 0.25$ (i.e., 25%), and the probability of picking index 1 is $3 / (1 + 3) = 0.75$ (i.e., 75%).

Example 1:

```

Input
["Solution","pickIndex"]
[[[]],[[]]]
Output
[null,0]

```

Explanation
Solution solution = new Solution([[]]);
solution.pickIndex(); // return 0. The only option is to return 0 since there is only one element in w .

Example 2:

```

Input
["Solution","pickIndex","pickIndex","pickIndex","pickIndex"]
[[[1,3]],[[]],[[]],[[]],[[]]]
Output
[null,1,1,1,0]

```

Explanation
Solution solution = new Solution([1, 3]);
solution.pickIndex(); // return 1. It is returning the second element (index = 1) that has a probability of 3/4.
solution.pickIndex(); // return 1
solution.pickIndex(); // return 1
solution.pickIndex(); // return 0. It is returning the first element (index = 0) that has a probability of 1/4.

Since this is a randomization problem, multiple answers are allowed.

All of the following outputs can be considered correct:

```

[null,1,1,1,0]
[null,1,1,1,1]
[null,1,1,0,0]
[null,1,1,0,1]
[null,1,0,0,0]
.....

```

and so on.

Constraints:

- $1 \leq w.length \leq 104$
- $1 \leq w[i] \leq 105$
- `pickIndex` will be called at most 104 times.

Peak Index in a Mountain Array
LeetCode · SimplyLeet · WalkCC · LeetCode · Editorial

Array · Binary Search
Likes: Denny Zhang

Problem:
You are given an integer mountain array arr of length n where the values increase to a peak element and then decrease.

Return the index of the peak element.
Your task is to solve it in O(log(n)) time complexity.

Example 1:

Input: arr = [0,1,0]

Output: 1

Example 2:

Input: arr = [0,2,1,0]

Output: 1

Example 3:

Input: arr = [0,10,5,2]

Output: 1

Constraints:

• 3 <= arr.length <= 105
• 0 <= arr[i] <= 106
• arr is guaranteed to be a mountain array.

>> Brute Force [Binary Search] Interview Prep

```
Python
# Brute Force Approach
class Solution:
    def peakIndexInMountainArray(self, arr):
        # Brute Force: Iterate through the array and find the peak index.
        for i, val in enumerate(arr):
            if val == target:
                return i
        return -1
```

```
Python
def peakIndexInMountainArray(arr):
    # Initialization pointers for the binary search
    left, right = 0, len(arr) - 1
    # Continue while there is more than one element in the search space
    while left < right:
        mid = (left + right) // 2
        # If the element at mid is increasing, move the left pointer to mid + 1
        if arr[mid] < arr[mid + 1]:
            left = mid + 1
        else:
            # Otherwise, the peak is at mid or to the left of mid
            right = mid
    # When left and right converge, we have the peak index
    return left
```

Example usage:
print(peakIndexInMountainArray([0, 1, 0])) # Output: 1

```
Python

func peakIndexInMountainArray(arr []int) int {
    left, right := 1, len(arr)-2
    for left < right {
        mid := (left + right) / 2
        if arr[mid] > arr[mid+1] {
            right = mid
        } else {
            left = mid + 1
        }
    }
    return left
}

```

Rust

Rust

```

impl Solution {
    pub fn peak_index_in_mountain_array(arr: Vec<i32>) -> i32 {
        let mut left = 1;
        let mut right = arr.len() - 2;
        while left < right {
            let mid = (left + right) / 2;
            if arr[mid] > arr[mid + 1] {
                right = mid;
            } else {
                left = left + 1;
            }
        }
        left as i32
    }
}

```

Rust

• String get(String key, int timestamp) Returns a value such that set was called previously, with timestamp, prev <= timestamp. If there are multiple such values, it returns the value associated with the largest timestamp, prev. If there are no values, it returns "".

Example 1:

```

Input
["TimeMap", "set", "get", "get", "set", "get", "get"]
[[], [{"foo", "bar", 1}], [{"foo", 1}], [{"foo", "bar2", 4}], [{"foo", 4}], [{"foo", 5}]
Output
[null, null, "bar", "bar", null, "bar2", "bar2"]

```

Explanation

```

TimeMap timeMap = new TimeMap();
timeMap.set("foo", "bar", 1); // store the key "foo" and value "bar" along with timestamp = 1.
timeMap.get("foo", 1); // return "bar"
timeMap.get("foo", 3); // return "bar", since there is no value corresponding to foo at timestamp 3 and timestamp 2, then the only value is at timestamp 1 is "bar".
timeMap.set("foo", "bar2", 4); // store the key "foo" and value "bar2" along with timestamp = 4.
timeMap.get("foo", 4); // return "bar2"
timeMap.get("foo", 5); // return "bar2"

```

Constraints:

- 1 <= key.length, value.length <= 100
- key and value consist of lowercase English letters and digits.
- 1 <= timestamp <= 107
- All the timestamps timestamp of set are strictly increasing.
- At most 2 * 105 calls will be made to set and get.

Python

Python

```

impl Solution {
    pub fn peak_index_in_mountain_array(arr: Vec<i32>) -> i32 {
        let mut left = 1;
        let mut right = arr.len() - 2;
        while left < right {
            let mid = (left + right) / 2;
            if arr[mid] > arr[mid + 1] {
                right = mid;
            } else {
                left = left + 1;
            }
        }
        left as i32
    }
}

```

Time Based Key-Value Store

LeetCode - Simplilearn - WUOLCC - LeetCode - Editorial

Hash Table - String - Binary Search - Design

Licic Grind 169

Problem:

Design a time-based key-value data structure that can store multiple values for the same key at different time stamps and retrieve the key's value at a certain timestamp.

Implement the TimeMap class:

- TimeMap() Initializes the object of the data structure.
- void set(String key, String value, int timestamp) Stores the key key with the value value at the given time timestamp.

```

# TimeMap class in Python with time-by-time comments.
class TimeMap:
    def __init__(self):
        # Initialize the dictionary to hold key and list of (timestamp, value) pairs.
        self.store = {}

    def set(self, key: str, value: str, timestamp: int) -> None:
        # Append the new (timestamp, value) pair for the given key.
        if key not in self.store:
            self.store[key] = []
        self.store[key].append((timestamp, value))

    def get(self, key: str, timestamp: int) -> str:
        # Return the value for the largest timestamp <= the given timestamp.
        if key not in self.store:
            return ""

        values = self.store[key]
        left, right = 0, len(values) - 1

        # Binary search for the rightmost index with timestamp <= given timestamp.
        while left < right:
            mid = (left + right) // 2
            if values[mid][0] <= timestamp:
                left = mid + 1
            else:
                right = mid - 1

        # If no valid timestamp exists, right will be -1.
        if right == -1:
            return ""
        return values[right][1]

# Example usage:
timeMap = TimeMap()
timeMap.set("foo", "bar", 1)
print(timeMap.get("foo", 1)) # Output: "bar"
print(timeMap.get("foo", 3)) # Output: "bar"
timeMap.set("foo", "bar2", 4)
print(timeMap.get("foo", 4)) # Output: "bar2"
print(timeMap.get("foo", 5)) # Output: "bar2"

```

Python

```

class TimeMap:
    def __init__(self):
        self.values = collections.defaultdict(list)
        self.timestamps = collections.defaultdict(list)

    def set(self, key: str, value: str, timestamp: int) -> None:
        self.values[key].append(value)
        self.timestamps[key].append(timestamp)

    def get(self, key: str, timestamp: int) -> str:
        if key not in self.timestamps:
            return ""
        i = bisect.bisectleft(self.timestamps[key], timestamp)
        return self.values[key][i - 1] if i > 0 else ""

```

```
Python

Capacity to Ship Packages Within D Days

LeetCode · SimplifyLeet · WalkCC · LeetCode · Editorial

Array · Binary Search

Licite Denny Zhang

Problem:

A conveyor belt has packages that must be shipped from one port to another within days days.

The ith package on the conveyor belt has a weight of weights[i]. Each day, we load the ship with packages on the conveyor belt (in the order given by weights). We may not load more weight than the maximum weight capacity of the ship.

Binary Search · LeetCode — By Pattern

— 2384 —

LeetCode

Return the least weight capacity of the ship that will result in all the packages on the conveyor belt being shipped within days days.

Example 1:

Input: weights = [1,2,3,4,5,6,7,8,9,10], days = 5

Output: 15

Explanation: A ship capacity of 15 is the minimum to ship all the packages in 5 days like this:

1st day: 1, 2, 3, 4, 5
2nd day: 6, 7
3rd day: 8
4th day: 9
5th day: 10

Note that the cargo must be shipped in the order given, so using a ship of capacity 14 and splitting the packages into parts like (2, 3, 4, 5), (1, 6, 7), (8), (9), (10) is not allowed.

Example 2:

Input: weights = [3,2,2,4,1,4], days = 3

Output: 6

Explanation: A ship capacity of 6 is the minimum to ship all the packages in 3 days like this:

1st day: 3, 2
2nd day: 2, 4
3rd day: 1, 4

Example 3:

Input: weights = [1,2,3,1,1], days = 4

Output: 3

Explanation:

1st day: 1
2nd day: 2
3rd day: 3
4th day: 1, 1

Constraints:

• 1 <= days <= weights.length <= 5 * 10⁴
• 1 <= weights[i] <= 500

Missing Element in Sorted Array

LeetCode - Simplify - WalkCC - LeetCode - Editorial

Array - Binary Search

List Premium 98

Problem:

Given an integer array nums which is sorted in ascending order and all of its elements are unique and given also an integer k, return the kth missing number starting from the leftmost number of the array.

Example 1:

Input: nums = [4,7,9,10], k = 1

Output: 5

Explanation: The first missing number is 5.

Example 2:

Input: nums = [4,7,9,10], k = 3

Output: 8

Explanation: The missing numbers are [5,6,8,...], hence the third missing number is 8.

Example 3:

Binary Search - LeetCode - By Pattern

— 2394 —

LeetCode

Input: nums = [1,2,4], k = 3
Output: 6
Explanation: The missing numbers are [3,5,6,7,...], hence the third missing number is 6.
Constraints:
• 1 <= nums.length <= 5 * 10⁴
• 1 <= nums[i] <= 10⁷
• nums is sorted in ascending order, and all the elements are unique.
• 1 <= k <= 10⁸

Follow up: Can you find a logarithmic time complexity (i.e., O(log(n))) solution?

Problem:

Given a string *s*, return the length of the longest repeating substrings. If no repeating substring exists, return 0.

Example 1:

Input: *s* = "abcd"
Output: 0
Explanation: There is no repeating substring.

Example 2:

Input: *s* = "abbaba"
Output: 2
Explanation: The longest repeating substrings are "ab" and "ba", each of which occurs twice.

Example 3:

Input: *s* = "aabcaabbaab"
Output: 3

#1533 Find the Index of the Large Integer

LeetCode - Simplify - Waffle - LeetCode - Editorial

Array - Binary Search - Interactive

LeetCode Premium 98

Problem:

We have an integer array `arr`, where all the integers in `arr` are equal except for one integer which is larger than the rest of the integers. You will not be given direct access to the array, instead, you will have an API `ArrayReader` which have the following functions:

- `int compareSub(int l, int r, int x, int y):` where $0 \leq l, r, x, y < \text{ArrayReader.length}$, $l < r$ and $x < y$. The function compares the sum of sub-array `arr[l..r]` with the sum of the sub-array `arr[x..y]` and returns: 1 if `arr[l..r] > arr[x..y]`, -1 if `arr[l..r] < arr[x..y]`, and 0 if `arr[l..r] == arr[x..y]`.
- 0 if `arr[l..r] > arr[x..y]`, -1 if `arr[l..r] < arr[x..y]`, and 0 if `arr[l..r] == arr[x..y]`.
- -1 if `arr[l..r] > arr[x..y]`, 1 if `arr[l..r] < arr[x..y]`, and 0 if `arr[l..r] == arr[x..y]`.

You are allowed to call `compareSub` 20 times at most. You can assume both functions work in $O(1)$ time.

Return the index of the array `arr` which has the largest integer.

Example 1:

Input: `arr = [7,7,7,7,10,7,7]`

Output: 4

Explanation: The following calls to the API `reader.compareSub(0, 0, 1, 1)` // returns 0 this is a query comparing the sub-array `(0, 0)` with the sub array `(1, 1)`, (i.e. compares `arr[0]` with `arr[1]`).

Thus we know that `arr[0]` and `arr[1]` doesn't contain the largest element.
`reader.compareSub(2, 2, 3, 3)` // returns 0, we can exclude `arr[2]` and `arr[3]`.
`reader.compareSub(4, 4, 5, 5)` // returns 1, thus for sure `arr[4]` is the largest element in the array.

Notice that we made only 3 calls, so the answer is valid.

Example 2:

Input: `nums = [6,6,12]`

Output: 2

Constraints:

- $2 \leq \text{arr.length} \leq 5 * 10^5$
- $1 \leq \text{arr}[i] \leq 100$
- All elements of `arr` are equal except for one element which is larger than all other elements.

Follow up:

- What if there are two numbers in `arr` that are bigger than all other numbers?
- What if there is one number that is bigger than other numbers and one number that is smaller than other numbers?

HARD

Median of Two Sorted Arrays

LeetCode - Binary Search - Divide and Conquer

Lists Grid 169

Problem:

Given two sorted arrays nums1 and nums2 of size m and n respectively, return the median of the two sorted arrays.

The overall run time complexity should be O(log(m+n)).

Example 1:

Input: nums1 = [1,3], nums2 = [2]

Output: 2.00000

Explanation: merged array = [1,2,3] and median is 2.

Example 2:

Input: nums1 = [1,2], nums2 = [3,4]

Output: 2.50000

Explanation: merged array = [1,2,3,4] and median is (2 + 3) / 2 = 2.5.

Constraints:

- nums1.length == m
- nums2.length == n
- 0 <= m <= 1000
- 0 <= n <= 1000
- 1 <= m + n <= 2000
- -100 <= nums1[i], nums2[i] <= 100

LeetCode

Given an integer array nums, return an integer array counts where counts[i] is the number of smaller elements to the right of nums[i].

Example 1:

Input: nums = [5,2,6,1]
Output: [2,1,0,0]

Explanation:

To the right of 5 there are 2 smaller elements (2 and 1).

To the right of 2 there is only 1 smaller element (1).

To the right of 6 there is 1 smaller element (1).

To the right of 1 there is 0 smaller element.

Example 2:

Input: nums = [-1]

Output: [0]

Example 3:

Input: nums = [-1,-1]

Output: [0,0]

Constraints:

• 1 <= nums.length <= 105

• -104 <= nums[i] <= 104

LeetCode

Python

```

insert(): maintaining a list in sorted order without having to sort the list after each insertion.
https://docs.python.org/3/library/bisect.html

bisect.bisect_left()
Locates the insertion point for x in a to maintain sorted order.

bisect.bisect_right() or bisect.bisect()
Similar to bisect_left(), but returns an insertion point which comes after (to the right of) any existing
entries of x in a.

bisect.insort_left(a, x, lo=0, hi=len(a), *, key=None)
Inserts x in a in sorted order.

Keep in mind that the O(log n) search is dominated by the slow O(n) insertion step.

bisect.insort_right(a, x, lo=0, hi=len(a), *, key=None)
bisect.insort(a, x, lo=0, hi=len(a), *, key=None)
Similar to insort_left(), but inserting x in a after any existing entries of x.

insort.bisect
== bisect.bisect
== bisect.bisect_right([1, 2, 3], 2)
2

insort.bisect_right([1, 2, 3], 2)

#410 **HARD**
Split Array Largest Sum
 LeetCode · Simplify · Walk · LeetCode · Editorial
 Array · Binary Search · Dynamic Programming · Greedy · Prefix Sum
 Little Denny Zhang

Problem:
 Given an integer array `nums` and an integer `k`, split `nums` into `k` non-empty subarrays such that the largest sum of any subarray is minimized.
 Return the minimized largest sum of the split.
 A subarray is a contiguous part of the array.
Example 1:
 Input: `nums = [7,2,5,10,8]`, `k = 2`
 Output: 18
 Explanation: There are four ways to split `nums` into two subarrays.
 The best way is to split it into `[7,2,5]` and `[10,8]`, where the largest sum among the two subarrays is only 18.
Example 2:

```

//
// Input: nums = [1,2,3,4,5], k = 2
// Output: 9
// Explanation: There are four ways to split nums into two subarrays.
// The best way is to split it into [1,2,3] and [4,5], where the largest sum among the two
// subarrays is only 9.
//
// Constraints:
// * 1 <= nums.length <= 1000
// * 0 <= nums[i] <= 106
// * 1 <= k <= min(50, nums.length)
//
// >> Brute Force (Binary Search) Interview Prep
//
// # Brute Force Approach
//
// class Solution:
//     def splitArray(self, nums: List[int], k: int) -> int:
//         # Brute Force O(n^k) - Linear scan instead of binary search
//         for i, val in enumerate(nums):
//             if val == target:
//                 return i
//
// Python
//
// # Python solution for Split Array Largest Sum
//
// def splitArray(nums, k):
//     # Helper function to determine if we can split array into k subarrays with max subarray sum <= mid
//     def canSplit(maxSum):
//         subarrayCount = 1 # start with one subarray
//         currentSum = 0
//         for num in nums:
//             if currentSum + num > maxSum:
//                 subarrayCount += 1 # start a new subarray
//                 currentSum = num # reset the sum with the current number
//             else:
//                 currentSum += num # add num to current subarray
//         return subarrayCount <= k # valid if we used k or fewer subarrays
//
//     low, high = max(nums), sum(nums) # boundaries for binary search
//     while low < high:
//         mid = (low + high) // 2 # candidate maximum subarray sum
//         if canSplit(mid):
//             high = mid # candidate is valid, try to find a smaller one
//         else:
//             low = mid + 1 # candidate too small, increase it
//     return low
//
// # Example usage:
//
// nums = [7,2,5,10,8]
// k = 2
// print(splitArray(nums, k)) # Expected output: 18
//

#668 **HARD**

Kth Smallest Number in Multiplication Table

LeetCode - Simplest - [WuJieCC](#) - [LeetCode](#) - [Editorial](#)

Math - Binary Search

Little Denny Zhang

Problem:

Nearly everyone has used the Multiplication Table. The multiplication table of size $m \times n$ is an integer matrix mat where $mat[i][j] = i \times j$ (1-indexed).

Given three integers m , n , and k , return the k th smallest element in the $m \times n$ multiplication table.

Example 1:

1	2	3
2	4	6
3	6	9

1	2	2	3	3	4	6	6	9
---	---	---	---	---	---	---	---	---

Input: m = 3, n = 3, k = 5

Output: 3

Explanation: The 5th smallest number is 3.

Example 2:

1	2	3
2	4	6

1	2	2	3	4	6
---	---	---	---	---	---

Input: m = 2, n = 3, k = 6

Output: 6

Explanation: The 6th smallest number is 6.

Constraints:

- $1 \leq m, n \leq 3 \times 10^4$

```

• 1 <= k <= m * n

#710 **HARD**
Random Pick with Blacklist
[LeetCode](#) - [SimplyLeet](#) - [WalkCC](#) - [LeetCode](#) - [Editorial](#)
[Array](#) - [Hash Table](#) - [Math](#) - [Binary Search](#) - [Sorting](#) - [Randomized](#)
[LeetCode](#) - [LeetCode](#) - [LeetCode](#)

Problem:
 You are given an integer n and an array of unique integers blacklist. Design an algorithm to pick a random integer in the range [0, n - 1] that is not in blacklist. Any integer that is in the mentioned range and not in blacklist should be equally likely to be returned.

Optimize your algorithm such that it minimizes the number of calls to the built-in random function of your language.

Implement the Solution class:

- `Solution(int n, int[] blacklist)` Initializes the object with the integer n and the blacklisted integers blacklist.
- `int pick()` Returns a random integer in the range [0, n - 1] and not in blacklist.

Example 1:

Input
 ["Solution", "pick", "pick", "pick", "pick", "pick", "pick", "pick"]
 [[7, [2, 3, 5]], [1], [1], [1], [1], [1], [1], [1]]

Output
 [null, 0, 4, 1, 6, 1, 0, 4]

Explanation
 Solution solution = new Solution(7, [2, 3, 5]);
 solution.pick(); // return 0, any integer from [0,1,4,6] should be ok. Note that for every call of pick,
 // 0, 1, 4, and 6 must be equally likely to be returned (i.e., with probability 1/4).
 solution.pick(); // return 4
 solution.pick(); // return 1
 solution.pick(); // return 6
 solution.pick(); // return 1
 solution.pick(); // return 0
 solution.pick(); // return 4

Constraints:

- 1 <= n <= 109
- 0 <= blacklist.length <= min(105, n - 1)
- 0 <= blacklist[i] < n
- All the values of blacklist are unique.
- At most 2 * 104 calls will be made to pick.

#774 **HARD** Minimize Max Distance to Gas Station

LeetCode · Simplified · WA/ACC · LeetCode · Editorial

Array · Binary Search

List: Denny Zhang

Problem:

You are given an integer array `stations` that represents the positions of the gas stations on the `x`-axis. You are also given an integer `k`.

You should add `k` new gas stations. You can add the stations anywhere on the `x`-axis, and not necessarily on an integer position.

Let `penalty()` be the maximum distance between adjacent gas stations after adding the `k` new stations.

Return the smallest possible value of `penalty()`. Answers within 10^{-6} of the actual answer will be accepted.

Example 1:

Input: `stations = [1,2,3,4,5,6,7,8,9,10]`, `k = 9`
Output: `0.50000`

Example 2:

Input: `stations = [23,24,36,39,46,56,57,65,84,90]`, `k = 1`
Output: `14.00000`

Constraints:

- $10 \leq \text{stations.length} \leq 2000$
- $0 \leq \text{stations}[i] \leq 10^8$
- `stations` is sorted in a strictly increasing order.
- $1 \leq k \leq 10^6$

HARD

Maximum Profit in Job Scheduling

LeetCode - SimplifyLeetCode - WalkCC - LeetCode - Editorial

Array - Binary Search - Dynamic Programming - Sorting

Lists Grid 169

Problem:

We have n jobs, where every job is scheduled to be done from $startTime[i]$ to $endTime[i]$, obtaining a profit of $profit[i]$.

You're given the $startTime$, $endTime$ and $profit$ arrays, return the maximum profit you can take such that there are no two jobs in the subset with overlapping time range.

If you choose a job that ends at time X you will be able to start another job that starts at time X .

Example 1:

Input: $startTime = [1,2,3,3]$, $endTime = [3,4,5,6]$, $profit = [50,10,40,70]$

Output: 120

Explanation: The subset chosen is the first and fourth job.

Time range $[1-3] \cup [4-6]$. we get profit of $120 = 50 + 70$.

Example 2:

Input: $startTime = [1,2,3,4,6]$, $endTime = [3,5,10,6,9]$, $profit = [20,20,100,70,60]$

Output: 150

Explanation: The subset chosen is the first, fourth and fifth job.

Profit obtained $150 = 20 + 70 + 60$.

Example 3:

Input: $startTime = [1,1,1]$, $endTime = [2,3,4]$, $profit = [5,6,4]$

Output: 6

Constraints:

$1 \leq startTime.length == endTime.length == profit.length \leq 5 \times 10^4$

$1 \leq startTime[i] < endTime[i] \leq 109$

$1 \leq profit[i] \leq 104$

LeetCode

Quick Review — Binary Search

24 questions · insights ·

#35 Search Insert Position [Easy]

Key Insights

- The array is sorted, enabling the use of binary search.
- Binary search achieves a time complexity of $O(\log n)$ which meets the problem constraints.
- When the target is not found during the search, the final low pointer represents the correct insertion index.

Space & Time

Time Complexity: $O(\log n)$ due to binary search.
Space Complexity: $O(1)$ as no extra space is used.

Solution

We use binary search to find the target in the sorted array. Initialize two pointers, low and high. At each iteration, compute the mid index. If the value at mid matches the target, return mid. If the target is less than the mid value, adjust the high pointer. If greater, adjust the low pointer. When the iterations finish without finding the target, return the low pointer, which represents the correct insertion index.

#69 Sqrt(x) [Easy]

Key Insights

- The problem can be solved efficiently using binary search.
- Instead of iterating from 0 to x , binary search narrows down the candidate square roots quickly.
- The algorithm should handle edge cases like $x = 0$ and $x = 1$.
- By checking mid $\neq$ mid against x , we can determine if we need to search in the lower or upper half.

Space & Time

Time Complexity: $O(\log x)$
Space Complexity: $O(1)$

Solution

We use a binary search approach to find the integer square root. Initialize two pointers, low and high, where low is set to 0 and high is set to x . For each iteration, calculate the mid value. If mid squared equals x , we have found the square root. If mid squared is less than x , record mid as a potential answer and move the low pointer to mid + 1. Otherwise, move the high pointer to mid - 1. Continue the search until low exceeds high, then return the last recorded candidate.

#278 First Bad Version [Easy]

Key Insights

- The API returns true for bad versions and all versions after a bad version.
- The problem is essentially about finding a transition point in a sorted sequence which calls for a binary search approach.
- The aim is to minimize the number of calls to isBadVersion by leveraging the ordered nature of the versions.

Space & Time

Time Complexity: $O(\log n)$
Space Complexity: $O(1)$

Solution

We use binary search to efficiently locate the first bad version. Initialize two pointers, left and right, at 1 and n respectively. At each step, compute the mid point and call isBadVersion(mid). If mid is bad, it indicates that the first bad version may be mid or to its left, so adjust right to mid. Otherwise, adjust left to mid + 1. Continue the process

Binary Search · LeetCode · By Pattern

— 2485 —

LeetCode

until the pointers converge. The converged pointer will be the first bad version. Key structures include simple integer variables for left, right, and mid, with binary search being the fundamental algorithm to reduce the search space logarithmically.

#374 Guess Number Higher or Lower [Easy]

Key Insights

- The problem can be effectively solved using binary search since the search space is sorted by nature (1 to n).
- Each API call helps to halve the search space, leading to an efficient solution.
- Be cautious with potential overflow when calculating the mid-point by using low + (high - low) // 2.

Space & Time

Time Complexity: $O(\log n)$ since we binary search the range.
Space Complexity: $O(1)$ as we use a constant amount of extra space.

Solution

We use a binary search algorithm to efficiently locate the target number. We initialize two pointers: low (1) and high (n). In each iteration, we compute the mid-point, then call the guess API. Based on the response:
– If guess(mid) returns 0, we have found the number.
– If it returns -1, it indicates that our guess is higher than the pick, so we update the high pointer to mid - 1.
– If it returns 1, it indicates that our guess is lower than the pick, so we update the low pointer to mid + 1. This approach guarantees a logarithmic time solution.

#704 Binary Search [Easy]

Key Insights

- Utilize binary search to achieve $O(\log n)$ runtime on a sorted array.
- Use two pointers to maintain the current search region.
- Narrow down the search range by comparing the middle element with the target.
- Return the index when the target is found; otherwise, return -1 if not found.

Space & Time

Time Complexity: $O(\log n)$
Space Complexity: $O(1)$

Solution

We use an iterative binary search algorithm. We initialize two pointers, left and right, to represent the current segment of the array that could contain the target. At each iteration, we compute the middle index and compare the element there with the target. If they match, we return the index. Otherwise, based on whether the target is smaller or larger than the middle element, we adjust our pointers to narrow the search to either the left or right half of the array. This process continues until the target is found or until the pointers cross, indicating that the target is not present. No extra data structures are used, making the space complexity $O(1)$.

#35 Search in Rotated Sorted Array [Medium]

Key Insights

- The array is originally sorted and then rotated at an unknown pivot.
- Use a modified binary search to accommodate the rotation.
- At every step, determine which half of the array is properly sorted.
- Narrow down the search based on the sorted half and the target's value.

Space & Time

Time Complexity: $O(\log n)$
Space Complexity: $O(1)$

Solution

We perform a binary search while accounting for the possibility that the array is rotated. At each iteration, we check if the left-to-mid portion is sorted. If it is, and the target falls within that range, we search the left half; otherwise,

Binary Search · LeetCode · By Pattern

— 2486 —

LeetCode

we search the right half. If the left half is not sorted, then the right half must be sorted, and similarly, we check if the target is in that sorted half. This approach ensures logarithmic time complexity while handling the rotation correctly.

#34 Find First and Last Position of Element in Sorted Array [Medium]

Key Insights

- The array is sorted, allowing the use of binary search.
- Two binary searches can efficiently find the leftmost (first) and rightmost (last) indices of the target.
- Handling edge cases where the target is not present by checking bounds.

Space & Time

Time Complexity: $O(\log n)$
Space Complexity: $O(1)$

Solution

The approach is to use binary search twice:

– The first binary search finds the leftmost occurrence of the target by continuing to search in the left half even after finding the target.
– The second binary search finds the rightmost occurrence by searching in the right half. The algorithm maintains pointers for the current search bounds and narrows the search space using comparisons. If the target is not found during the first binary search, the solution immediately returns [-1, -1]. This method leverages the sorted property of the array, ensuring $O(\log n)$ time complexity with constant extra space.

#153 Find Minimum in Rotated Sorted Array [Medium]

Key Insights

- The rotated sorted array consists of two sorted subarrays.
- A modified binary search can be used to locate the pivot point where the rotation occurs.
- By comparing the middle element to the rightmost element, we can decide which half of the array contains the minimum.

Space & Time

Time Complexity: $O(\log n)$
Space Complexity: $O(1)$

Solution

We use a binary search approach. Initialize two pointers, left and right, at the start and end of the array. While left is less than right, calculate the middle index. If the middle element is greater than the right element, then the minimum is in the right half, so move the left pointer to mid + 1; otherwise, the minimum must be in the left half including mid, so adjust the right pointer to mid. When the loop terminates, left equals right and points to the minimum element. This approach leverages the properties of the rotated sorted array to achieve logarithmic time complexity.

#300 Longest Increasing Subsequence [Medium]

Key Insights

- A dynamic programming solution with $O(n^2)$ time complexity exists, but we focus on an optimized approach.
- Using binary search and a dp array, we can achieve $O(n \log n)$ time.
- The dp array maintains the smallest possible tail for increasing subsequences of various lengths.
- For each number, perform binary search to decide if it can extend or replace a value in dp.

Space & Time

Time Complexity: $O(n \log n)$ where n is the length of nums
Space Complexity: $O(n)$ for storing the dp array

Solution

We use a dynamic programming approach combined with binary search. The idea is to maintain a dp array where dp[i] holds the smallest tail value for any increasing subsequence with length i+1. For each number in the array, we perform a binary search on dp to find its correct insertion position:

Binary Search · LeetCode · By Pattern

— 2487 —

LeetCode

Space Complexity: $O(1)$ – Only constant extra space is used.

Solution

We use a binary search strategy:

- Initialize two pointers, left and right, at the beginning and end of the array. – In each iteration, calculate mid. If arr[mid] is less than arr[mid + 1], then the peak is in the right half; otherwise, it is in the left half. – When left equals right, we have found the peak index. This approach leverages the mountain array properties and ensures an $O(\log n)$ solution.

#581 Time Based Key-Value Store [Medium]

Key Insights

- Use a dictionary (hash table) to map each key to a list of (timestamp, value) pairs.
- Timestamps are strictly increasing when setting the values, which allows efficient appending.
- For getting the value, perform a binary search on the list of timestamps to find the latest timestamp that is <= the queried timestamp.
- If no valid timestamp exists, return an empty string.

Space & Time

Time Complexity: – set operation: $O(1)$ per call (amortized).
– get operation: $O(\log N)$ per call, where N is the number of timestamps stored for the key.
Space Complexity: $O(\text{total number of set calls})$, to store all (timestamp, value) pairs.

Solution

We use a hash table to store keys mapping to a list of their timestamps and corresponding values. Since the timestamps are inserted in strictly increasing order, the list remains sorted. For the get operation, a binary search is applied to quickly locate the appropriate value for a given timestamp. This approach minimizes the lookup time and efficiently handles the problem constraints.

#1011 Capacity to Ship Packages Within D Days [Medium]

Key Insights

- The minimal possible capacity is the maximum value in weights; no ship can carry a package heavier than its capacity.
- The maximum possible capacity is the sum of all weights; this allows shipping all packages in one day.
- The problem is monotonic: if a capacity C works, any capacity greater than C will also work.
- Use binary search on the capacity range and a greedy approach to simulate shipping for each candidate capacity.

Space & Time

Time Complexity: $O(n * \log(\text{sum(weights)}))$ where n is the number of packages.
Space Complexity: $O(1)$ additional space.

Solution

The solution employs binary search to find the minimum ship capacity. Start by setting the search bounds: the lower bound is the maximum weight (since each package must be shipped individually if needed) and the upper bound is the sum of all weights (shipping everything in one go). For each midpoint capacity in the binary search, use a greedy method to simulate the shipping process—accumulating weights until adding another package would exceed the candidate ship capacity, at which point you increment the day count. If the number of days required exceeds D , the capacity is insufficient and the lower bound is increased; otherwise, adjust the upper bound. Continue until the bounds converge.

#1060 Missing Element in Sorted Array [Medium]

Key Insights

- The array is sorted and every element is unique.

Binary Search · LeetCode · By Pattern

— 2489 —

LeetCode

– if the number is larger than all elements, we append it, effectively extending the current longest subsequence. – Otherwise, we replace the first element in dp that is greater than or equal to the current number to keep the tail as small as possible. This process ensures that dp remains sorted and its length gives the length of the longest increasing subsequence.

#362 Design Hit Counter [Medium]

Key Insights

- Use a sliding window of 300 seconds to count hits.
- Since timestamps are monotonically increasing, outdated hits can be removed from the front.
- A queue (or circular array) is an efficient data structure to maintain and remove expired hit records.
- Grouping consecutive hits at the same timestamp can optimize space.

Space & Time

Time Complexity: $O(1)$ per hit and getHits operation on average, since each hit is enqueued and later dequeued only once.
Space Complexity: $O(W)$ where W is the window size (300 seconds) in the worst case.

Solution

The solution uses a queue (or deque) data structure where each element stores a (timestamp, count) pair. When a hit is recorded, if the last element of the queue shares the same timestamp, then its count is incremented; otherwise, a new element is added. When getHits(timestamp) is called, the algorithm removes elements from the front of the queue whose timestamp is out of the 300-second window relative to the current timestamp, and then sums the counts of the remaining elements to return the result. This ensures that only relevant hits within the past 5 minutes are counted. The design scales well when hit frequency is high because hits at the same timestamp are grouped together instead of inserting individual records.

#528 Random Pick with Weight [Medium]

Key Insights

- Build a prefix sum array from the weights.
- Calculate the total sum of the weights.
- Generate a random number in the range [1, total sum] and use binary search to find the corresponding index in the prefix sum array.
- Using binary search ensures efficient selection in $O(\log n)$ time for each call of pickIndex().

Space & Time

Time Complexity: $O(n)$ for constructing the prefix sum array, and $O(\log n)$ per pickIndex() call.
Space Complexity: $O(n)$ for storing the prefix sum array.

Solution

The solution leverages a prefix sum array where each entry at index i represents the cumulative sum of weights up to i . After computing the total weight, a random integer is generated between 1 and the total sum (inclusive). A binary search is then used to find the first index where the prefix sum is greater than or equal to the random number. This approach ensures that the index is selected with a probability proportional to its weight.

#852 Peak Index in a Mountain Array [Medium]

Key Insights

- The array is strictly increasing up to a peak and then strictly decreasing.
- A binary search technique is applicable because the array exhibits a single transition point (peak) between increasing and decreasing order.
- By comparing mid and mid+1, we can decide which half of the array to continue the search in.

Space & Time

Time Complexity: $O(\log n)$ – The binary search approach reduces the search interval by half at each step.

Binary Search · LeetCode · By Pattern

— 2488 —

LeetCode

- For any index i , the number of missing numbers up to that point can be computed as $\text{nums}[i] - \text{nums}[0] - i$.
- When $\text{miss}(i)$ is less than k , the k th missing element is further to the right.
- Use binary search to find the smallest index where the count of missing numbers is greater than or equal to k .
- If all missing numbers before the last array element are counted and the k th missing still hasn't been reached, calculate the result by continuing past the last element.

Space & Time

Time Complexity: $O(\log n)$
Space Complexity: $O(1)$

Solution

We compute the number of missing elements until an index i with the formula: $\text{miss}(i) = \text{nums}[i] - \text{nums}[0] - i$. We then use binary search over the indices to find the smallest index where $\text{miss}(i) \geq k$. If the binary search index equals the length of the array, it means the k th missing number lies beyond the last element. Otherwise, the k th missing number is derived as: $\text{nums}[\text{index}] - 1 + k - \text{miss}(\text{index} - 1)$. This approach uses binary search for logarithmic time and does not require extra auxiliary data structures.

#1062 Longest Repeating Substring [Medium]

Key Insights

- Use binary search to efficiently check for the existence of a repeating substring of a given length.
- Apply a rolling hash technique to compute hash values for substrings in $O(1)$ time after initial preprocessing.
- Use a hash set to detect duplicate hash values (indicating a repeating substring).
- Adjust binary search bounds based on whether a repeating substring of the current length exists.
- Alternative approaches include dynamic programming and suffix arrays, but the binary search with rolling hash is efficient and conceptually clean.

Space & Time

Time Complexity: $O(n \log n)$ on average, where n is the length of the string. (Each binary search step takes $O(n)$ time for computing rolling hashes.)
Space Complexity: $O(n)$ for storing hash values in the hash set.

Solution

The solution uses binary search to decide on the candidate length L of the repeating substring. For each candidate length L , we use a rolling hash to compute hash values for all substrings of length L and store them in a hash set. If any hash is repeated, it confirms the presence of a repeating substring of length L , and we try a longer length. Otherwise, we decrease the candidate length. The rolling hash is computed using a base (26, for lowercase letters) and a modulus (2^{32} to limit integer overflow) which allows efficient hash recomputation for sliding windows. This approach efficiently narrows down the maximum repeating substring length.

#1533 Find the Index of the Large Integer [Medium]

Key Insights

- Use binary search to efficiently narrow down the position of the unique large value.
- At each step, divide the candidate range into two halves (or almost two halves when the range size is odd) and use compareSub to determine which half contains the large integer.
- Comparing two subarrays of equal length will reveal the region that contains the extra value via the sum difference.
- Handle odd-length ranges carefully by isolating the middle element if needed.

Space & Time

Time Complexity: $O(\log n)$ – because binary search is performed over the range.
Space Complexity: $O(1)$ – only a few pointers are maintained, no additional space is required.

Solution

The solution applies a binary search approach over the array indices. At every iteration:

Binary Search · LeetCode · By Pattern

— 2490 —

LeetCode

• Calculate the current segment length. • If the length is even, split the segment evenly and compare the left half versus the right half using `compareSub`. • If the length is odd, compare two halves of equal size while ignoring the middle element. If the sums are equal, then the middle index holds the large value. • Update the search bounds based on the result of `compareSub`. • Continue until the search space is reduced to one index, which is the answer. This method ensures that you locate the large integer with $O(\log n)$ calls to `compareSub`, well within the limit of 20 calls.

#4 Median of Two Sorted Arrays [Hard]

Key Insights

- The median divides the sorted array into two equal halves.
- We can perform binary search on the smaller array to partition both arrays correctly.
- We need to ensure that every element in the left partition is less than or equal to every element in the right partition.
- Edge cases must be handled when partitions are at the boundaries of either array.

Space & Time

Time Complexity: $O(\log(\min(m, n)))$
Space Complexity: $O(1)$

Solution

The solution uses a binary search technique on the smaller array. We define a partition index i for `nums1` and compute the corresponding index j for `nums2` such that $i + j$ equals half of the total number of elements. The algorithm checks if the largest element on the left side of `nums1` (if any) is less than or equal to the smallest element on the right side of `nums1`, and vice versa for `nums2`. If the condition holds, we have found the correct partition and compute the median. If not, adjust the binary search range until the correct partition is found. This partitioning strategy allows us to find the median in logarithmic time.

#315 Count of Smaller Numbers After Self [Hard]

Key Insights

- The brute force solution takes $O(n^2)$ time, which is too slow for large input arrays.
- An efficient approach leverages the concept of Merge Sort to both sort the array and count the number of smaller elements by tracking the number of elements that "jump over" during the merge step.
- Other efficient methods include Binary Indexed Trees (Fenwick Tree) or Balanced Binary Search Trees.

Space & Time

Time Complexity: $O(n \log n)$ on average due to the merge sort based approach.
Space Complexity: $O(n)$ for auxiliary arrays used during sorting and counting.

Solution

We use a modified Merge Sort to sort the array while counting the number of smaller elements to the right. We keep track of the original indices by pairing each element with its index. During the merge process, when an element from the left subarray is placed into the temporary array, we add the count of elements from the right subarray that have already been placed (since these represent smaller elements that were to its right). This efficient divide and conquer strategy guarantees an overall $O(n \log n)$ time complexity. Care must be taken to update the counts based on indices and during the merge step.

#410 Split Array Largest Sum [Hard]

Key Insights

- Use binary search over the answer: the candidate value is the maximum subarray sum.
- The lower bound of the search is $\max(\text{nums})$ and the upper bound is $\sum(\text{nums})$.
- A greedy approach is used to check if a candidate maximum sum allows splitting `nums` into at most k subarrays.
- Adjust the binary search bounds based on the feasibility check.

Binary Search • LeetCode • By Pattern

— 2493 —

LeetCode

Space & Time

Time Complexity: $O(n * \log(\sum(\text{nums})))$ • n elements are processed for each binary search iteration.
Space Complexity: $O(1)$ • Constant extra space is used.

Solution

The solution employs binary search to determine the smallest maximum subarray sum possible. We set the initial lower bound to the maximum element and the upper bound to the total sum of the array. For each candidate value `mid`, we check if the array can be split into k or fewer subarrays without any subarray sum exceeding `mid` using a greedy approach. If possible, we try to lower the candidate; if not, we increase the candidate. This continues until the optimal solution is found.

#668 Kth Smallest Number in Multiplication Table [Hard]

Key Insights

- The table elements are not fully sorted row-wise or column-wise globally, but there is a pattern that can be exploited.
- For any candidate number x , we can count how many numbers in the table are less than or equal to x by summing over rows: for row i , there are $\text{min}(x // i, n)$ numbers.
- Binary search can be used over the range $[1, m * n]$ to find the smallest x such that the count is at least k .
- The counting function is the key to connecting the candidate value with the order statistic.

Space & Time

Time Complexity: $O(m * \log(m * n))$
Space Complexity: $O(1)$

Solution

We use binary search over the possible values in the multiplication table, which range from 1 to $m * n$. For each midpoint x in the binary search, we compute the number of elements in the table that are less than or equal to x by iterating over each row and summing up $\text{min}(x // i, n)$. This count tells us whether the k th smallest element is to the left or right of x . We then adjust the binary search boundaries accordingly. The approach leverages the multiplicative structure of the table and the monotonicity of the counting function.

#710 Random Pick with Blacklist [Hard]

Key Insights

- The valid output range has a total count of available numbers $W = n - \text{len}(\text{blacklist})$.
- Instead of repeatedly generating random numbers and checking against a set, we can transform the range into a contiguous block $[0, W - 1]$ and map any blacklist number within that block to a valid number in the upper range.
- Mapping is precomputed: for any blacklisted number x in $[0, W - 1]$, assign it a valid number from $[W, n - 1]$ that is not blacklisted.

This approach ensures $O(1)$ pick time after an $O(b)$ precomputation where $b = \text{length of blacklist}$.

Space & Time

Time Complexity: constructor - $O(b)$ for initializing data structures, $\text{pick}()$ - $O(1)$ per call.
Space Complexity: $O(b)$ for storing the blacklist set and mapping.

Solution

We compute the count of valid numbers, $W = n - \text{len}(\text{blacklist})$. For numbers in the blacklist that are less than W , we need to map them to a valid number from the range $[W, n - 1]$. To do this, we first store all blacklist numbers in the higher range $[W, n - 1]$ in a set for quick lookup. Then for each blacklisted value in $[0, W - 1]$, we iterate from W upwards to find a number that is not blacklisted and assign it in a mapping. During the `pick()` function, we generate a random integer r in $[0, W - 1]$. If r is in our mapping, we return its corresponding mapped value; otherwise, we return r as it is already a valid number.

Climbing Stairs

LeetCode • SimplifyIt • WalkCC • LeetCode • Editorial
Math • Dynamic Programming • Memoization

Lists Grid 169

Problem:

You are climbing a staircase. It takes n steps to reach the top.

Each time you can either climb 1 or 2 steps. In how many distinct ways can you climb to the top?

Example 1:

Input: $n = 2$
Output: 2
Explanation: There are two ways to climb to the top.
1. 1 step + 1 step
2. 2 steps

Example 2:
Input: $n = 3$
Output: 3
Explanation: There are three ways to climb to the top.
1. 1 step + 1 step + 1 step
2. 1 step + 2 steps
3. 2 steps + 1 step

Constraints:

- $1 \leq n \leq 45$

LeetCode 169
Problem:

```

Dynamic Programming · LeetCode - By Pattern — 2500 —

LeetCode

You are given an array prices where prices[i] is the price of a given stock on the i-th day. You want to maximize your profit by choosing a single day to buy one stock and choosing a different day in the future to sell that stock. Return the maximum profit you can achieve from this transaction. If you cannot achieve any profit, return 0.

Example 1:

Input: prices = [7,1,5,3,6,4]
Output: 5
Explanation: Buy on day 2 (price = 1) and sell on day 5 (price = 6), profit = 6-1 = 5. Note that buying on day 2 and selling on day 1 is not allowed because you must buy before you sell.

Example 2:

Input: prices = [7,6,4,3,1]
Output: 0
Explanation: In this case, no transactions are done and the max profit = 0.

Constraints:

- 1 <= prices.length <= 105
- 0 <= prices[i] <= 104

[7] Dynamic Programming - Pattern Solution (stored optimal)

Python

def maxProfit(prices):
    # Initialize max_profit as infinity and max_profit as 0
    m1_price = float('inf')
    max_profit = 0
    # Iterate through each price in the list
    for price in prices:
        # Update the minimum price if current price is lower
        if price < m1_price:
            m1_price = price
        else:
            # Calculate current profit and update max_profit if it is higher
            max_profit = max(max_profit, price - m1_price)
    return max_profit

# Example usage:
# result = maxProfit([7,1,5,3,6,4])
# print(result) # Output should be 5

```

```

C++
#include <vector>
#include <algorithm>
#include <iostream>
using namespace std;

class Solution {
public:
    int maxProfit(vector<int>& prices) {
        // Initialize maxPrice to maximum integer and maxProfit to 0
        int maxPrice = INT_MAX;
        int maxProfit = 0;
        // Loop through each price in the vector
        for (int price : prices) {
            // Update maxPrice if the current price is lower
            maxPrice = min(maxPrice, price);
            // Calculate profit for current day and update maxProfit if higher
            maxProfit = max(maxProfit, price - maxPrice);
        }
        return maxProfit;
    }
};

// Example usage:
// int main() {
//     Solution sol;
//     vector<int> prices = {7,1,5,3,6,4};
//     cout << sol.maxProfit(prices); // Output should be 5
//     return 0;
// }

```

#5 MEDIUM Longest Palindromic Substring

LeetCode's Longest Palindromic Substring · WikiCS · LeetCode · Editorial

String · Dynamic Programming

Lists: Grind 169

Problem: Given a string s, return the longest palindromic substring in s.

Example 1:

Input: s = "babab"
Output: "bab"
Explanation: "aba" is also a valid answer.

Example 2:

Input: s = "cbbd"
Output: "bb"

Constraints:

- 1 ≤ s.length ≤ 1000
- s consist of only digits and English letters.

MEDIUM

Maximum Subarray

LeetCode · Simple · Easy · Medium · Hard · LeetCode · Editorial

Array · Dynamic Programming · Divide and Conquer

Like · Grind 189

Problem:

Given an integer array `nums`, find the subarray with the largest sum, and return its sum.

Example 1:

Input: `nums = [-2,1,-3,4,-1,2,1,-5,4]`

Output: `6`

Explanation: The subarray `[4,-1,2,1]` has the largest sum `6`.

Example 2:

Input: `nums = [1]`

Output: `1`

Explanation: The subarray `[1]` has the largest sum `1`.

Example 3:

Input: `nums = [5,4,-1,7,8]`
Output: `23`
Explanation: The subarray `[5,4,-1,7,8]` has the largest sum `23`.

Constraints:

- `1 <= nums.length <= 105`
- `-104 <= nums[i] <= 104`

Follow up: If you have figured out the $O(n)$ solution, try coding another solution using the divide and conquer approach, which is more subtle.

Jump Game

LeetCode · SimplyLeet · WalkCC · LeetCode · Editorial

Array · Dynamic Programming · Greedy

Like · 600

Problem: You are given an integer array `nums`. You are initially positioned at the array's first index, and each element in the array represents your maximum jump length at that position. Return `true` if you can reach the last index, or `false` otherwise.

Example 1:

Input: `nums = [2,3,1,1,4]`
Output: `true`
Explanation: Jump 1 step from index 0 to 1, then 3 steps to the last index.

Example 2:

Input: `nums = [3,2,1,0,4]`
Output: `false`
Explanation: You will always arrive at index 3 no matter what. Its maximum jump length is 0, which makes it impossible to reach the last index.

Constraints:

• `1 <= nums.length <= 10^4`

>> Brute Force [Dynamic Programming] Interview Prep

Python

```

# Brute Force Approach
class Solution:
    def canJump(self, nums):
        # Brute Force O(N^2) - recursion: try every reachable position
        def can_reach(i):
            if i == len(nums) - 1: return True
            for step in range(1, nums[i] + 1):
                if can_reach(i + step): return True
            return False
        return can_reach(0)

```

Python

```

# Function to determine if you can reach the last index of the array
def canJump(nums):
    # Initialize maxReach which is the max index reachable at start (index 0)
    maxReach = 0
    # Iterate through each element and its index
    for i, jump in enumerate(nums):
        # If current index is greater than maxReach, return False
        if i > maxReach:
            return False
        # Update maxReach with the maximum of current maxReach and i + jump length at index i
        maxReach = max(maxReach, i + jump)
        # If current maxReach is already at or beyond the last index, return True
        if maxReach == len(nums) - 1:
            return True
    # Return True if the end is reachable after processing all indices
    return True

```

Example usage:

```

# print(canJump([2,3,1,1,4])) # Expected output: True
# print(canJump([3,2,1,0,4])) # Expected output: False

```

Python

```

class Solution:
    def canJump(self, nums: List[int]) -> bool:
        i = 0
        reach = 0
        while i < len(nums) and i <= reach:
            reach = max(reach, i + nums[i])
            i += 1
        return i == len(nums)

Listo Grind 189

Problem:

There is a robot on an $m \times n$ grid. The robot is initially located at the top-left corner (i.e., `grid[0][0]`). The robot tries to move to the bottom-right corner (i.e., `grid[m - 1][n - 1]`). The robot can move either down or right at any point in time.

Given the two integers m and n , return the number of possible unique paths that the robot can take to reach the bottom-right corner.

The test cases are generated so that the answer will be less than or equal to $2^{31} - 1$.

Example 1:

Input: $m = 3, n = 7$

Output: 28

Example 2:

Input: $m = 3, n = 2$

Output: 3

Explanation: From the top-left corner, there are a total of 3 ways to reach the bottom-right

LeetCode
```

Problem:
Given two strings word1 and word2, return the minimum number of operations required to convert word1 to word2.

You have the following three operations permitted on a word:

- Insert a character
- Delete a character
- Replace a character

Example 1:

Input: word1 = "horse", word2 = "ros"

Output: 3

Explanation:

horse -> rorse (replace 'h' with 'r')

rorse -> rose (remove 'r')

rose -> ros (remove 'e')

Example 2:

Input: word1 = "intention", word2 = "execution"

Output: 5

Explanation:

intention -> inention (remove 't')

inention -> enention (replace 'i' with 'e')

enention -> exention (replace 'n' with 'x')

exention -> exection (replace 'n' with 'c')

exection -> execution (insert 'u')

Constraints:

- 0 <= word1.length, word2.length <= 500
- word1 and word2 consist of lowercase English letters.

Decode Ways

LeetCode · [SimplifyLeet](#) · [WuKCC](#) · [LeetCode](#) · [Editorial](#)
 String · [Dynamic Programming](#)
 Lists · [Grind 189](#)

Problem:

You have intercepted a secret message encoded as a string of numbers. The message is decoded via the following mapping:

"1" -> 'A' "2" -> 'B' ... "25" -> 'Y' "26" -> 'Z'

However, while decoding the message, you realize that there are many different ways you can decode the message because some codes are contained in other codes ("2" and "5" vs "25").

For example, "11106" can be decoded into:

- "AAJF" with the grouping (1, 1, 10, 6)
- "KJF" with the grouping (11, 10, 6)

- The grouping (1, 11, 06) is invalid because "06" is not a valid code (only "6" is valid).

Note: there may be strings that are impossible to decode. Given a string s containing only digits, return the number of ways to decode it. If the entire string cannot be decoded in any valid way, return 0.

The test cases are generated so that the answer fits in a 32-bit integer.

Example 1:

Input: s = "12"

Output: 2

Explanation:

"12" could be decoded as "AB" (1 2) or "L" (12).

Example 2:

Input: s = "226"

Output: 3

Explanation:

"226" could be decoded as "BZ" (2 26), "VF" (22 6), or "BBF" (2 2 6).

Example 3:

Input: s = "06"

Output: 0

Explanation:

"06" cannot be mapped to "f" because of the leading zero ("6" is different from "06"). In this case, the string is not a valid encoding, so return 0.

Constraints:

- 1 <= s.length <= 100
- s contains only digits and may contain leading zero(s).

Python

Python

```
# Python solution using dynamic programming
def num_decodings(s: str) -> int:
    # If the string starts with '0', it's not decodable
    if not s or s[0] == '0':
        return 0

MEDIUM

Maximum Product Subarray

LeetCode - SimplyList - WalleCC - LeetCode - Editorial

Array - Dynamic Programming

Like · 100

Problem:

Given an integer array `nums`, find a subarray that has the largest product, and return the product.

The test cases are generated so that the answer will fit in a 32-bit integer.

Note that the product of an array with a single element is the value of that element.

Example 1:

Input: `nums = [2,3,-2,4]`

Output: 6

Explanation: [2,3] has the largest product 6.

Example 2:

Input: `nums = [-2,0,-1]`

Output: 0

Explanation: The result cannot be 2, because [-2,-1] is not a subarray.

Constraints:

- $1 \leq \text{nums.length} \leq 2 \times 10^4$
- $-10 \leq \text{nums}[i] \leq 10$

#198 **MEDIUM**
House Robber
[LeetCode](#) · [SolutionSet](#) · [WalkCC](#) · [LeetCode](#) · [Editorial](#)
Array · Dynamic Programming
Lists Grid 169

Problem:

You are a professional robber planning to rob houses along a street. Each house has a certain amount of money stashed, the only constraint stopping you from robbing each of them is that adjacent houses have security systems connected and it will automatically contact the police if two adjacent houses were broken into on the same night.

Given an integer array `nums` representing the amount of money of each house, return the maximum amount of money you can rob tonight without alerting the police.

Example 1:

Input: `nums = [1,2,3,1]`
Output: 4
Explanation: Rob house 1 (money = 1) and then rob house 3 (money = 3).
Total amount you can rob = 1 + 3 = 4.

Example 2:

Input: `nums = [2,7,9,3,1]`
Output: 12
Explanation: Rob house 1 (money = 2), rob house 3 (money = 9) and rob house 5 (money = 1).
Total amount you can rob = 2 + 9 + 1 = 12.

Constraints:

- 1 <= `nums.length` <= 100
- 0 <= `nums[i]` <= 400

#256 MEDIUM
Paint House
LeetCode · SimpleCode · WalkCC · LeetCode · Editorial
Array · Dynamic Programming
List: Premium 98

Problem:
There is a row of n houses, where each house can be painted one of three colors: red, blue, or green. The cost of painting each house with a certain color is different. You have to paint all the houses such that no two adjacent houses have the same color.

The cost of painting each house with a certain color is represented by an n x 3 cost matrix costs.

• For example, costs[0][0] is the cost of painting house 0 with the color red; costs[1][2] is the cost of painting house 1 with color green, and so on..

Return the minimum cost to paint all houses.

Example 1:
Input: costs = [[17,2,17],[16,16,5],[14,3,19]]
Output: 18
Explanation: Paint house 0 into blue, paint house 1 into green, paint house 2 into blue.
Minimum cost: 2 + 5 + 3 = 10.

Example 2:
Input: costs = [[7,6,2]]
Output: 2

Constraints:
• costs.length == n
• costs[i].length == 3
• 1 <= n <= 100

Best Time to Buy and Sell Stock with Cooldown

LeetCode · Simplify · [MathCE](#) · [LeetCode](#) · Editorial

Array · Dynamic Programming

List: Denny Zhang

Problem:

You are given an array prices where prices[i] is the price of a given stock on the ith day.

Find the maximum profit you can achieve. You may complete as many transactions as you like (i.e., buy one and sell one share of the stock multiple times) with the following restrictions:

- After you sell your stock, you cannot buy stock on the next day (i.e., cooldown one day).

Note: You may not engage in multiple transactions simultaneously (i.e., you must sell the stock before you buy again).

Example 1:

Input: prices = [1,2,3,0,2]

Output: 3

Explanation: transactions = [buy, sell, cooldown, buy, sell]

Example 2:

Input: prices = [1]

Output: 0

Constraints:

- 1 <= prices.length <= 5000
- 0 <= prices[i] <= 1000

Combination Sum IV

LeetCode · SimplifyTest · WalkCC · LeetCode · Editorial

Array · Dynamic Programming

Lists Grid 169

Problem:

Given an array of distinct integers `nums` and a target integer `target`, return the number of possible combinations that add up to `target`.

The test cases are generated so that the answer can fit in a 32-bit integer.

Example 1:

Input: `nums = [1,2,3]`, `target = 4`

Output: 7

Explanation:

The possible combination ways are:

(1, 1, 1, 1)

(1, 1, 2)

(1, 2, 1)

(1, 3)

(2, 1, 1)

(2, 2)

(3, 1)

Note that different sequences are counted as different combinations.

Example 2:

Input: `nums = [9]`, `target = 3`

Output: 0

Constraints:

• `1 <= nums.length <= 200`

• `1 <= nums[i] <= 1000`

• All the elements of `nums` are unique.

• `1 <= target <= 1000`

Partition Equal Subset Sum

LeetCode · Simple · Medium · LeetCode · LeetCode · Editorial

Array · Dynamic Programming

Lists · Grind 169

Problem:

Given an integer array `nums`, return `true` if you can partition the array into two subsets such that the sum of the elements in both subsets is equal or false otherwise.

Example 1:

Input: `nums = [1,5,11,5]`

Output: `true`

Explanation: The array can be partitioned as `[1, 5, 5]` and `[11]`.

Example 2:

Input: `nums = [1,2,3,5]`

Output: `false`

Explanation: The array cannot be partitioned into equal sum subsets.

Constraints:

- `1 <= nums.length <= 200`
- `1 <= nums[i] <= 100`

LeetCode

#435 MEDIUM

Non-overlapping Intervals

LeetCode · SimplifyIt · WsAAC · LeetCode · Editorial

Array · Dynamic Programming · Greedy · Sorting

Units Grind 189

Problem:

Given an array of intervals where intervals[i] = [starti, endi], return the minimum number of intervals you need to remove to make the rest of the intervals non-overlapping.

Note that intervals which only touch at a point are non-overlapping. For example, [1, 2] and [2, 3] are non-overlapping.

Example 1:

Input: intervals = [[1,2],[2,3],[3,4],[1,3]]

Output: 1

Explanation: [1,3] can be removed and the rest of the intervals are non-overlapping.

Example 2:

Input: intervals = [[1,2],[1,2],[1,2]]

Output: 2

Explanation: You need to remove two [1,2] to make the rest of the intervals non-overlapping.

Example 3:

Input: intervals = [[1,2],[2,3]]

Output: 0

Explanation: You don't need to remove any of the intervals since they're already non-overlapping.

Constraints:

- 1 <= intervals.length <= 105
- intervals[i].length == 2
- 5 * 104 <= starti < endi <= 5 * 104

Longest Palindromic Subsequence

LeetCode · SimplifyLess · WalkCC · LeetCode · Editorial

String · Dynamic Programming

Licite Danny Zhang

Problem:

Given a string *s*, find the longest palindromic subsequence's length in *s*.

A subsequence is a sequence that can be derived from another sequence by deleting some or no elements without changing the order of the remaining elements.

Example 1:

Input: *s* = "bbbab"

Output: 4

Explanation: One possible longest palindromic subsequence is "bbbb".

Example 2:

Input: *s* = "cbbd"

Output: 2

Explanation: One possible longest palindromic subsequence is "bb".

Constraints:

- 1 <= s.length <= 1000
- s consists only of lowercase English letters.

Longest Common Subsequence

LeetCode · SimplyLeetCode · WubACCC · LeetCode · Editorial

String · Dynamic Programming

Little Sheng Zhang

Problem:

Given two strings text1 and text2, return the length of their longest common subsequence. If there is no common subsequence, return 0.

A subsequence of a string is a new string generated from the original string with some characters (can be none) deleted without changing the relative order of the remaining characters.

• For example, "ace" is a subsequence of "abcde".

A common subsequence of two strings is a subsequence that is common to both strings.

Example 1:

Input: text1 = "abcde", text2 = "ace"
Output: 3
Explanation: The longest common subsequence is "ace" and its length is 3.

Example 2:
Input: text1 = "abc", text2 = "abc"
Output: 3
Explanation: The longest common subsequence is "abc" and its length is 3.

Example 3:
Input: text1 = "abc", text2 = "def"
Output: 0
Explanation: There is no such common subsequence, so the result is 0.

Constraints:

- 1 <= text1.length, text2.length <= 1000
- text1 and text2 consist of only lowercase English characters.

```
Python
# Python3 code to find the longest common subsequence length
def longestCommonSubsequence(text1: str, text2: str) -> int:
    n, m = len(text1), len(text2)
    # Initialize a 2D DP table filled with zeros
    dp = [[0] * (n + 1) for _ in range(m + 1)]

    # Build the DP table bottom-up
    for i in range(1, n + 1):
        for j in range(1, m + 1):
            # If characters match, extend the subsequence length by 1
            if text1[i - 1] == text2[j - 1]:
                dp[i][j] = dp[i - 1][j - 1] + 1
            else:
                # Otherwise, choose the maximum from the left or top cell
                dp[i][j] = max(dp[i - 1][j], dp[i][j - 1])

    return dp[n][m]

# Example usage
if __name__ == "__main__":
    text1 = "abcde"
    text2 = "ace"
    print(longestCommonSubsequence(text1, text2)) # Output: 3
```

```

        }
        return f[n][m]
    }
}
```

Input: s = "ab", p = ".*a"
Output: true
Explanation: ".*" means "zero or more (x) of any character (.)".

Constraints:

- 1 <= s.length <= 20
- 1 <= p.length <= 20
- s contains only lowercase English letters.
- p contains only lowercase English letters, '.', and '*'.
- It is guaranteed for each appearance of the character '*', there will be a previous valid character to match.

Regular Expression Matching

[LeetCode](#) · [SimpleList](#) · [WahCCE](#) · [LeetCode](#) · [Editorial](#)

String · Dynamic Programming · Recursion

List: Denny Zhang

Problem:

Given an input string s and a pattern p, implement regular expression matching with support for '.' and '*' where:

• '.' Matches any single character.

• '*' Matches zero or more of the preceding element.

Return a boolean indicating whether the matching covers the entire input string (not partial).

Example 1:

Input: s = "aa", p = "a"
Output: false
Explanation: "a" does not match the entire string "aa".

Example 2:

Input: s = "aa", p = "a*"
Output: true
Explanation: 'a' means zero or more of the preceding element, 'a'. Therefore, by repeating 'a' once, it becomes "aa".

Example 3:

```
class Solution {
    def isMatch(s: str, p: str) -> bool:
        n = len(s)
        m = len(p)
        dp = [[False] * (m + 1) for _ in range(n + 1)]
        dp[0][0] = True

        def isMatch(i: int, j: int) -> bool:
            return j == 0 and p[j] == '.' or s[i] == p[j]

        for j, c in enumerate(p):
            if c == '.' and dp[0][j - 1]:
                dp[0][j] = True

        for i in range(1, n + 1):
            for j in range(1, m + 1):
                # The minimum index of c in p
                subpattern = dp[i + 1][j - 1]
                subpattern = isMatch(i, j - 1) and dp[i][j - 1]
                dp[i][j] = True if subpattern or subpattern
                elif isMatch(i, j):
                    dp[i + 1][j + 1] = dp[i][j]

        return dp[n][m]
```

Python

```
class Solution:
    def isMatch(self, s: str, p: str) -> bool:

Best Time to Buy and Sell Stock III

LeetCode · SimplifyLeet · WalkCC · LeetCode · Editorial

Array · Dynamic Programming

Like · Denny Zhang

Problem:

You are given an array prices where prices[i] is the price of a given stock on the i-th day.

Find the maximum profit you can achieve. You may complete at most two transactions.

Note: You may not engage in multiple transactions simultaneously (i.e., you must sell the stock before you buy again).

Example 1:

Input: prices = [3,3,5,0,0,3,1,4]

Output: 6

Explanation: Buy on day 4 (price = 0) and sell on day 6 (price = 3), profit = 3-0 = 3.

Then buy on day 7 (price = 1) and sell on day 8 (price = 4), profit = 4-1 = 3.

Example 2:

Input: prices = [1,2,3,4,5]

Output: 4

Explanation: Buy on day 1 (price = 1) and sell on day 5 (price = 5), profit = 5-1 = 4.

Note that you cannot buy on day 1, buy on day 2 and sell then later, as you are engaging multiple transactions at the same time. You must sell before buying again.

Example 3:

Input: prices = [7,6,4,3,1]

Output: 0

Explanation: In this case, no transaction is done, i.e. max profit = 0.

Constraints:

- 1 <= prices.length <= 105
- 0 <= prices[i] <= 105

#132 **HARD**
Palindrome Partitioning II
 LeetCode - [Description](#) - [Solution2](#) - [LeetCode](#) - [Editorial](#)
 String - [Dynamic Programming](#)
 List: Denny Zhang

Problem:
 Given a string s, partition s such that every substring of the partition is a palindrome.
 Return the minimum cuts needed for a palindrome partitioning of s.

Example 1:
 Input: s = "aab"
 Output: 1
 Explanation: The palindrome partitioning ["aa","b"] could be produced using 1 cut.

Example 2:
 Input: s = "a"
 Output: 0

Example 3:
 Input: s = "ab"
 Output: 1

Constraints:
 • 1 <= s.length <= 2000
 • s consists of lowercase English letters only.

Python
 Python

```

def minCut(s: str) -> int:
    n = len(s)
    # Pre-compute palindrome table where isPal[i][j] is True if s[i:j+1] is a palindrome.
    isPal = [[False] * n for _ in range(n)]
    # dp[i] will store the minimum cuts required for substring s[0...i]
    dp = [0] * n
    for i in range(n):
        min_cut = 4 # Maximum cuts (not every character)
        for j in range(0, i + 1):
            # Check if s[j:i+1] is a palindrome.
            if s[j] == s[i] and (i - j < 2 or isPal[j + 1][i - 1]):
                isPal[j][i] = True # Mark substring as palindrome.
            # If the minimum starts at index 0, no cut is needed.
            min_cut = 0 if j == 0 else min(min_cut, dp[j - 1] + 1)

Burst Balloons

LeetCode · SimplifyLeetCode · WubACE · LeetCode · Editorial

Array · Dynamic Programming

Little Denny Zhang

Problem:

You are given n balloons, indexed from 0 to n - 1. Each balloon is painted with a number on it represented by an array nums. You are asked to burst all the balloons.

If you burst the i-th balloon, you will get nums[i - 1] * nums[i] * nums[i + 1] coins. If i - 1 or i + 1 goes out of bounds of the array, then treat it as if there is a balloon with a 1 painted on it.

Return the maximum coins you can collect by bursting the balloons wisely.

Example 1:

Input: nums = [3,1,5,8]

Output: 167

Explanation:

nums = [3,1,5,8] -> [3,5,8] -> [3,8] -> [8] -> []

coins = 3*1*5 + 3*5*8 + 1*5*8 + 1*8*1 = 167

Example 2:

Input: nums = [1,5]

Output: 10

Constraints:

- n == nums.length
- 1 <= n <= 300
- 0 <= nums[i] <= 100

#1000 **HARD**
Minimum Cost to Merge Stones
LeetCode — SimplyLeetCode — LeetCode — Editorial
Array — Dynamic Programming
Like · Donny Zhang

Problem:
There are n piles of stones arranged in a row. The i th pile has $stones[i]$ stones.
A move consists of merging exactly k consecutive piles into one pile, and the cost of this move is equal to the total number of stones in these k piles.
Return the minimum cost to merge all piles of stones into one pile. If it is impossible, return -1 .
Example 1:
Input: $stones = [3,2,4,1]$, $k = 2$
Output: 20
Explanation: We start with $[3, 2, 4, 1]$.
We merge $[3, 2]$ for a cost of 5, and we are left with $[5, 4, 1]$.
We merge $[4, 1]$ for a cost of 5, and we are left with $[5, 5]$.
We merge $[5, 5]$ for a cost of 10, and we are left with $[10]$.
The total cost was 20, and this is the minimum possible.
Example 2:
Input: $stones = [3,2,4,1]$, $k = 3$
Output: -1

Dynamic Programming — LeetCode — By Pattern — 2693 —

LeetCode

Explanation: After any merge operation, there are 2 piles left, and we can't merge anymore.
So the task is impossible.
Example 3:
Input: $stones = [3,5,1,2,6]$, $k = 3$
Output: 25
Explanation: We start with $[3, 5, 1, 2, 6]$.
We merge $[5, 1, 2]$ for a cost of 8, and we are left with $[3, 8, 6]$.
We merge $[3, 8, 6]$ for a cost of 17, and we are left with $[17]$.
The total cost was 25, and this is the minimum possible.

Constraints:
 $n == stones.length$
 $1 \leq n \leq 30$
 $1 \leq stones[i] \leq 100$
 $2 \leq k \leq 30$

LeetCode

Quick Review — Dynamic Programming 24 questions · insights · complexity · solution

#70 Climbing Stairs [Easy]

Key Insights

- The problem can be solved using dynamic programming because the solution for a given step depends on the solutions of the previous two steps.
- The recurrence relation is: $ways[i] = ways[i-1] + ways[i-2]$.
- Base cases: when there is 1 step, there is 1 way; when there are 2 steps, there are 2 ways.
- This is analogous to the Fibonacci sequence, shifting indices accordingly.

Space & Time

Time Complexity: $O(n)$

Space Complexity: $O(n)$ (can be optimized to $O(1)$ using constant space)

Solution

We use a dynamic programming approach to build a solution gradually. The idea is that to reach step i , you could have come from step $i-1$ (taking one step) or from step $i-2$ (taking two steps). Therefore, the total number of ways to reach step i is the sum of ways to reach step $i-1$ and $i-2$. We initialize $dp[1] = 1$ and $dp[2] = 2$, and iterate from 3 to n to fill dp . Each code solution below uses this approach with comments to explain the logic.

#121 Best Time to Buy and Sell Stock [Easy]

Key Insights

- Traverse the list of prices once while keeping track of the minimum price encountered so far.
- At each day, calculate the profit if you sold the stock on that day.
- Update the maximum profit when the current profit exceeds the previous maximum.
- The optimal solution makes a single pass through the array with constant space usage.

Space & Time

Time Complexity: $O(n)$ - requires one pass through the prices array.

Space Complexity: $O(1)$ - only a few extra variables are used.

Solution

We solve the problem using a simple linear scan. We maintain two key variables: one for the minimum price seen so far and another for the maximum profit calculated so far. As we iterate, we continuously update the minimum price if a lower price is found, and then compute the potential profit at the current price. If this profit exceeds the current maximum profit, we update the maximum profit. The final maximum profit is returned after iterating through all prices.

#5 Longest Palindromic Substring [Medium]

Key Insights

- Every palindrome is centered around a character (for odd-length) or a pair of characters (for even-length).
- Expand from each center until the substring is no longer a palindrome.
- Update the longest palindrome when a longer one is found during the expansion.
- The solution employs a two-pointer technique without extra storage for dynamic programming tables.

Space & Time

Time Complexity: $O(n^2)$ in the worst case as we expand around each center.

Space Complexity: $O(1)$, excluding the space required for the output substring.

Solution

Space & Time

Time Complexity: $O(m)$

n

Space Complexity: $O(m)$

n - can be optimized to $O(n)$ using a 1D DP array.

Solution

We can solve the problem using a dynamic programming approach. The idea is to create a 2D DP table where each cell (i, j) represents the number of ways to reach that cell. Since the robot can only come from above or from the left, we update the DP table as follows:
- Initialize $dp[0][0] = 1$ for all j (only one way to move right in the first row). - Initialize $dp[i][0] = 1$ for all i (only one way to move down in the first column). - For each other cell, compute $dp[i][j] = dp[i-1][j] + dp[i][j-1]$. The final answer will be at $dp[m-1][n-1]$.
The combinatorial alternative computes $C(m+n-2, m-1)$ or $C(m+n-2, n-1)$ using basic factorial arithmetic, which is efficient for the given constraints.

#72 Edit Distance [Medium]

Key Insights

- This is a classic dynamic programming problem.
- Use a 2D DP table where $dp[i][j]$ represents the minimum edit distance between $word1[0..i-1]$ and $word2[0..j-1]$.
- Base cases: converting an empty string to a string of length j requires j insertions, and vice versa.
- Transition: if characters match then $dp[i][j] = dp[i-1][j-1]$, otherwise take minimum among insertion, deletion, and replacement operations and add 1.

Space & Time

Time Complexity: $O(mn)$

n , where m and n are the lengths of $word1$ and $word2$ respectively.

Space Complexity: $O(m)$

n due to the DP table used for storing computed distances.

Solution

We use a dynamic programming approach by constructing a 2D table dp of size $(m+1) \times (n+1)$, where m and n are the lengths of $word1$ and $word2$. Each $dp[i][j]$ holds the minimum number of operations needed to convert the first i characters of $word1$ to the first j characters of $word2$. The algorithm includes the following steps:
- Initialize the base cases: $dp[i][0] = i$ (converting an empty $word2$ to i characters of $word1$ requires i deletions) and $dp[0][j] = j$ (converting i characters of $word1$ to an empty $word2$ requires i insertions).
- Iterate over each character in $word1$ and $word2$: if the current characters are equal, no additional operation is needed and $dp[i][j] = dp[i-1][j-1]$. Otherwise, choose the best operation among insertion ($dp[i][j-1]$), deletion ($dp[i-1][j]$), or substitution ($dp[i-1][j-1]$) and add 1. - The answer is found in $dp[m][n]$.
This method reliably computes the edit distance using a systematic DP approach, ensuring that all subproblems are solved and reused efficiently.

#91 Decode Ways [Medium]

Key Insights

- A digit '0' cannot be mapped on its own; it must be part of '10' or '20'.
- Use dynamic programming where $dp[i]$ represents the number of ways to decode the substring $s[0..i-1]$.
- For each index i , if the digit at position $i-1$ is non-zero, add $dp[i-1]$ to $dp[i]$.
- If the two-digit number formed by $s[i-2]$ and $s[i-1]$ is between 10 and 26, add $dp[i-2]$ to $dp[i]$.
- Initialize $dp[0]$ as 1 (an empty string has one way to be decoded).

Space & Time

Dynamic Programming · LeetCode · By Pattern

— 2705 —

LeetCode

Dynamic Programming · LeetCode · By Pattern

— 2706 —

LeetCode

Time Complexity: $O(n)$, where n is the length of the string.

Space Complexity: $O(n)$, due to the dp array (which can be optimized to $O(1)$).

Solution

We solve the problem using a dynamic programming approach. We initialize a dp array where $dp[i]$ indicates the number of ways to decode the substring $s[0..i-1]$. We set $dp[0] = 1$ since an empty string is trivially decodable. We loop through the string, and at each step:

- If $s[i-1]$ is not '0', we add $dp[i-1]$ to $dp[i]$ because $s[i-1]$ can be mapped to a valid letter. - If the substring $s[i-2..i]$ (for $i > 2$) forms a valid two-digit number between 10 and 26, we add $dp[i-2]$ to $dp[i]$. This cumulative approach yields the total ways to decode the string, and if the string starts with '0' or contains invalid sequences, $dp[n]$ will eventually be 0.

#152 Maximum Product Subarray [Medium]

Key Insights

- Maintain both the maximum and minimum product at the current index because a negative number can swap the max and min.
- A subarray must be contiguous.
- Use dynamic programming to update both the maximum product and the minimum product ending at each index.
- Resetting the product in case of a zero is crucial since the product becomes 0.

Space & Time

Time Complexity: $O(n)$ - The solution iterates through the array once.

Space Complexity: $O(1)$ - Constant space is used for tracking products.

Solution

The solution uses an iterative dynamic programming approach. At each index, compute the maximum product (maxEndingHere) and minimum product (minEndingHere) ending at that index. If the current element is negative, swap these two values, because multiplying a negative with a minimum product (possibly negative) might yield a larger product. After processing each element, update the global maximum. This method handles edge cases like zeros and negatives efficiently with constant additional space.

#198 House Robber [Medium]

Key Insights

- The problem can be solved using Dynamic Programming.
- For each house, decide whether to rob it or not.
- Recurrence relation: $dp[i] = \max(dp[i-1], dp[i-2] + \text{currentHouseMoney})$
- Use iterative computation to keep track of the optimal solutions without needing extra space for the entire dp array.

Space & Time

Time Complexity: $O(n)$, where n is the number of houses.

Space Complexity: $O(1)$, using only two variables to track the previous decisions.

Solution

We use a dynamic programming approach by iterating through each house in the array. At each step, we consider two scenarios: either we rob the current house (and add its money to the total from two houses ago) or we skip it (keeping the optimal solution up to the previous house). By using two variables to store these intermediate results, we achieve an optimized space complexity of $O(1)$.

#256 Paint House [Medium]

Key Insights

- The choice for painting each house depends on the previous house's color choices.
- Use dynamic programming to accumulate the cost while ensuring adjacent houses do not have the same color.

Dynamic Programming - LeetMastery - By Patterns

— 2707 —

LeetMastery

- The state of each house can be represented by the minimum cost when the house is painted a specific color, computed using the minimal costs of the previous house from the other two colors.
- The problem only requires updating the cost matrix in-place for optimal space usage.

Space & Time

Time Complexity: $O(n)$, where n is the number of houses.

Space Complexity: $O(1)$ extra space if the input matrix is modified in place.

Solution

We use a dynamic programming approach with iterative in-place updating of the cost matrix. For each house starting from the second one, we update the cost for each color by adding the minimal cost of painting the previous house with either of the other two colors. This guarantees we never use the same color for adjacent houses while accumulating the minimal total cost. The final answer is the minimum value for the last house.

#309 Best Time to Buy and Sell Stock with Cooldown [Medium]

Key Insights

- Use Dynamic Programming to solve the problem.
- Maintain three states to represent:
 - $s0$: the state where you are ready to buy (not holding any stock).
 - $s1$: the state where you are holding a stock.
 - $s2$: the cooldown state encountered right after selling a stock.
- Transition between states:
 - Transition into $s0$ can come from staying in $s0$ or coming out from the cooldown state $s2$.
 - To enter $s1$, you either continue holding your stock, or buy a stock using the profit available from $s0$.
 - The only way to reach $s2$ is by selling the stock from $s1$.
- The final answer is determined by the maximum profit when you are not holding a stock (i.e., $\max(s0, s2)$).

Space & Time

Time Complexity: $O(n)$, where n is the number of days.

Space Complexity: $O(1)$, since only a few variables are maintained for the states.

Solution

The solution involves updating three state variables for each day:

- $s0$ (ready to buy) is updated as the maximum of the previous $s0$ and the previous cooldown $s2$.
- $s1$ (holding a stock) is updated as the maximum of the previous $s1$ or buying today with the profit from $s0$ minus the current price.
- $s2$ (cooldown) is updated by selling the stock held in $s1$ (i.e., previous $s1$ plus the current price). At the end of the iteration, the maximum profit will be in state $s0$ (ready to buy) or $s2$ (cooldown), since remaining in $s1$ means you are holding a stock, which does not constitute a realized profit.

#377 Combination Sum IV [Medium]

Key Insights

- Use dynamic programming to count the number of valid combinations.
- The order in which numbers are picked matters, making this akin to permutation counting.
- Initialize a DP table where $dp[i]$ represents the number of ways to form the sum i .
- $dp[0]$ is initialized to 1 since there is one way to form a sum of 0 (by choosing nothing).
- For each sum i from 1 to target, iterate over nums and update $dp[i]$ based on $dp[i - num]$ when $i > \text{num}$.
- For negative numbers, the problem becomes unbounded due to potential infinite combinations; hence a constraint on the combination length is required to make it well-defined.

Space & Time

Time Complexity: $O(\text{target} * n)$, where n is the length of nums.

Space Complexity: $O(\text{target})$, for the dp array of size target + 1.

Dynamic Programming - LeetMastery - By Patterns

— 2708 —

LeetMastery

Solution

The problem is solved using a bottom-up dynamic programming approach. We create a dp array where each $dp[i]$ represents the number of possible combinations to reach the sum i . We iterate from 1 up to target, and for each sum, we check every number in nums. If the number can contribute to the current sum ($i - \text{num} > 0$), we add the number of ways to form the remainder ($i - \text{num}$) to $dp[i]$. This ensures that every possible permutation is counted. When negative numbers are allowed in the input, the potential for an infinite number of combinations arises unless we impose additional constraints, such as limiting the length of the combination.

#416 Partition Equal Subset Sum [Medium]

Key Insights

- The total sum of the array must be even, otherwise, partitioning into two equal subsets is impossible.
- The problem can be transformed into a "subset sum" problem where we need to check if there exists a subset of numbers that sums to half of the total sum.
- A dynamic programming approach can efficiently decide if such a subset exists.

Space & Time

Time Complexity: $O(n * \text{target})$, where target is half of the total sum.

Space Complexity: $O(\text{target})$, using a one-dimensional DP array.

Solution

First, compute the total sum of the array. If the total is odd, return false since an odd number cannot be equally partitioned. Next, set the target sum to half of the total. Use a dynamic programming array $dp[i]$ where $dp[i]$ represents whether a subset with sum i is achievable. Initialize $dp[0]$ as true because a subset sum of 0 is always possible. Then, for each number in the array, iterate through the dp array backwards from target to the number's value and update $dp[i]$ to true if $dp[i - \text{num}]$ is true. Ultimately, if $dp[\text{target}]$ is true, the array can be partitioned into two subsets with equal sum.

#435 Non-overlapping Intervals [Medium]

Key Insights

- Sorting is the key: By sorting intervals by their end times, we can greedily choose the optimal set of non-overlapping intervals.
- Greedy approach: Always select the interval that ends the earliest, as it leaves maximum room for subsequent intervals.
- Counting removals: The answer is the total number of intervals minus the count of intervals selected by this greedy approach.
- Edge observation: Intervals that touch at the boundary are not overlapping, so the check uses ">=" instead of ">".

Space & Time

Time Complexity: $O(n \log n)$ due to sorting the intervals.

Space Complexity: $O(n)$ if considering the storage for the sorted list or $O(1)$ if sorting in-place.

Solution

The solution involves first sorting the intervals by their end times. Initialize a variable to track the end of the last chosen interval. Iterate over the sorted intervals: if the current interval's start is greater than or equal to the last chosen interval's end, update the last end and include this interval in the non-overlapping set. Otherwise, count the interval as one that must be removed. The final answer is the removal count, which is computed as the total number of intervals minus the count of non-overlapping intervals selected.

#516 Longest Palindromic Subsequence [Medium]

Key Insights

- The problem can be solved efficiently using dynamic programming.
- A 2D DP table is used where $dp[i][j]$ represents the length of the longest palindromic subsequence in the substring $s[i..j]$.

Dynamic Programming - LeetMastery - By Patterns

— 2709 —

LeetMastery

- If the characters at the two ends of the substring match ($s[i] == s[j]$), they contribute to the palindrome length.
- Otherwise, the solution is the maximum sequence length by either excluding the left or the right character.
- The approach builds the solution from smaller substrings (length 1) to the entire string.

Space & Time

Time Complexity: $O(n^2)$ where n is the length of the string.

Space Complexity: $O(n^2)$ due to the usage of a 2D DP table.

Solution

We solve this problem using a bottom-up dynamic programming approach. We create a 2D table $dp[i][j]$ such that $dp[i][j]$ stores the longest palindromic subsequence length for the substring $s[i..j]$. For any single character, $dp[i][i]$ is 1. For substrings of length greater than 1, if the characters at positions i and j ($s[i]$ and $s[j]$) match, then $dp[i][j] = dp[i+1][j-1] + 2$. If they do not match, we take the maximum of $dp[i+1][j]$ and $dp[i][j-1]$. Finally, the $dp[i][i-1]$ holds the result for the entire string.

#576 Out of Boundary Paths [Medium]

Key Insights

- Use Dynamic Programming (DP) as the state is defined by (current row, current column, moves remaining).
- Transitions are made from a cell to its four adjacent cells.
- If the ball moves out of bounds, it contributes to one valid path.
- States can be memoized to avoid recomputation and optimize the recursive solution.

Space & Time

Time Complexity: $O(\text{rows} * \text{cols} * m^n)$, since we compute each state at most once.

Space Complexity: $O(\text{rows} * \text{cols} * m^n)$ for the memoization table.

Solution

We use a recursive dynamic programming (or memoization) approach. Define a function $dp(i, j, \text{movesLeft})$ that returns the number of ways to move out of bounds starting from cell (i, j) with movesLeft moves remaining. For each move from the current cell, check:

- If the cell is out of bounds, return 1 (base case).
- If no moves are left ($\text{movesLeft} == 0$) and we are still inside, return 0.
- Otherwise, use recursion to explore all four directions and sum the paths. Store results in a memoization table to avoid recomputation, then return the computed value modulo $10^9 + 7$.

#1143 Longest Common Subsequence [Medium]

Key Insights

- The problem is well-suited for a dynamic programming approach.
- Use a 2D table where $dp[i][j]$ stores the length of the longest common subsequence for $\text{text1}[0..i-1]$ and $\text{text2}[0..j-1]$.
- If the characters match at the current position, extend the subsequence by 1 from $dp[i-1][j-1]$; otherwise, take the maximum from $dp[i-1][j]$ or $dp[i][j-1]$.
- Filling the table in a bottom-up manner ensures that all subproblems are solved optimally.

Space & Time

Time Complexity: $O(m * n)$, where m and n are the lengths of text1 and text2 .

Space Complexity: $O(m * n)$ for maintaining the 2D DP table. Space can be optimized to $O(\min(m, n))$ if needed.

Solution

This solution uses a dynamic programming approach with a 2D array dp to record the lengths of common subsequences at each substring pair. We initialize a table of dimensions $(m+1) \times (n+1)$ with zeros, where m and n are the lengths of text1 and text2 . We iterate over both strings, comparing characters. If they match, we set $dp[i][j] = dp[i-1][j-1] + 1$, otherwise we choose the maximum from $dp[i-1][j]$ and $dp[i][j-1]$. The final answer is found at $dp[m][n]$.

LeetMastery

#10 Regular Expression Matching [Hard]

Key Insights

- Use recursion or dynamic programming to simulate matching as the '*' operator can affect the current and following characters.
- The '.' operator is a wildcard that matches any single character.
- When encountering a '*' in the pattern, consider both skipping the preceding element or consuming one character from the string if it matches.
- Using memoization helps to save intermediate results and efficiently process overlapping subproblems.

Space & Time

Time Complexity: $O(m)$

n where $m = \text{length}(s)$ and $n = \text{length}(p)$, due to exploring each subproblem combination.

Space Complexity: $O(m)$

n for storing the memoization table in the dynamic programming or recursive approach.

Solution

The solution uses a top-down recursive strategy with memoization to efficiently match the string against the pattern. For each character position i in s and p , we check if they match directly or if the pattern character is '*' to allow any match. When encountering '*' in the pattern, two possibilities are explored: either the '*' stands for zero occurrences of the preceding element, or if there is a valid match, it accounts for one occurrence and we proceed further in the string while maintaining the same pattern index. The memoization aspect prevents repeated computations of the same (i, j) state in the recursion, resulting in an improved overall runtime.

#115 Distinct Subsequences [Hard]

Key Insights

- Use dynamic programming to build the solution by comparing characters of s and t .
- Define a 2D dp table where $dp[i][j]$ represents the number of ways to form the first j characters of t using the first i characters of s .
- The recurrence relation:
 - If $s[i-1]$ equals $t[j-1]$, then include both the cases of matching this character as well as skipping it: $dp[i][j] = dp[i-1][j-1] + dp[i-1][j]$.
 - If they do not match, then simply skip the current character of s : $dp[i][j] = dp[i-1][j]$.
- Initialize $dp[0][0] = 1$ for all i since an empty t can always be formed.
- The final answer is $dp[s.length][t.length]$.

Space & Time

Time Complexity: $O(n * m)$, where n is the length of s and m is the length of t .

Space Complexity: $O(n * m)$, which can be optimized to $O(n)$ with careful row reuse.

Solution

We use a dynamic programming approach with a 2D table. The table has dimensions $(\text{len}(s) + 1) \times (\text{len}(t) + 1)$. Each cell $dp[i][j]$ stores the number of distinct subsequences from the first i characters of s that match the first j characters of t .

Steps:

- Initialize $dp[0][0] = 1$ for every i , because an empty t is a subsequence of any prefix of s .
- Iterate over each character s (outer loop) and for each, iterate over t (inner loop).
- For every character in s , if it equals the current character in t , update $dp[i][j]$ as the sum of the ways by using or skipping this character. Otherwise, carry over the previous count.
- Return $dp[\text{len}(s)][\text{len}(t)]$ as the result.

#123 Best Time to Buy and Sell Stock III [Hard]

Key Insights

- The problem requires the optimal selection of at most two buy-sell transactions.

Dynamic Programming - LeetMastery - By Patterns

— 2711 —

LeetMastery

- One effective strategy is to split the problem into two parts:
 - For each day i , calculate the maximum profit obtainable from day 0 to i with one transaction.
 - For each day j , calculate the maximum profit obtainable from day i to the end with one transaction.
- Finally, for each day, the sum of these two profits (left and right) gives a candidate answer.
- Alternatively, a state-based dynamic programming approach can track 4 states corresponding to the two transactions.

Space & Time

Time Complexity: $O(n)$ where n is the number of days

Space Complexity: $O(n)$ due to extra arrays used for forward and backward computations (this can be optimized to $O(1)$ with a state variable approach)

Solution

We use a two-pass dynamic programming approach. In the first pass (forward), we compute an array 'leftProfits' where $\text{leftProfits}[i]$ is the maximum profit from day 0 to day i with one transaction. We do this by keeping track of the minimum price observed so far and calculating the profit if sold on day i . In the second pass (backward), we compute an array 'rightProfits' where $\text{rightProfits}[i]$ is the maximum profit obtainable from day i to the last day with one transaction by tracking the maximum price seen in reverse order. Finally, for every index i , the sum $\text{leftProfits}[i] + \text{rightProfits}[i]$ represents the maximum profit achievable by completing the first transaction on or before day i and the second transaction starting from day i . The answer is the maximum sum over all i .

#132 Palindrome Partitioning II [Hard]

Key Insights

- Precompute a 2D table $isPal$ where $isPal[i][j]$ indicates if the substring $s[i..j]$ is a palindrome.
- Use dynamic programming: $dp[i]$ represents the minimum cuts needed for the substring $s[0..i]$.
- For every index i , iterate over all possible starting indices j . If $s[j..i]$ is a palindrome, update $dp[i]$ using $dp[j-1] + 1$ (or 0 if j is 0).
- Time complexity is dominated by the $O(n^2)$ palindrome checking and state transitions.

Space & Time

Time Complexity: $O(n^2)$

Space Complexity: $O(n+2)$ (due to the 2D table for palindrome checks, plus $O(n)$ for the dp array)

Solution

The solution relies on dynamic programming with a two-step approach. First, precompute a 2D table $isPal$ where each cell indicates if a substring is a palindrome. This is done in $O(n^2)$ time by leveraging the fact that a substring $s[i..j]$ is a palindrome if the characters at the ends match and the inner substring $s[i+1..j-1]$ is also a palindrome (or if the length is less than 3). Then, use a dp array where $dp[i]$ holds the minimum number of cuts needed for the substring $s[0..i]$. For each i , check every index j ($0 \leq j \leq i$) if $s[j..i]$ is a palindrome, update $dp[i]$ to be the minimum of its current value and $dp[j-1] + 1$ (with a special case when j is 0, meaning no cut is needed). This two-phase approach efficiently breaks down the problem and computes the answer while avoiding redundant palindrome checks.

#132 Burst Balloons [Hard]

Key Insights

- Transform the problem by adding virtual balloons with value 1 at both ends to simplify edge handling.
- Use interval dynamic programming where $dp[i][j]$ represents the maximum coins that can be obtained by bursting all balloons between indices i and j (inclusive).
- Realize that the order of bursting balloons matters; choose the last balloon to burst in each interval to break dependencies into independent subproblems.
- The solution involves iterating over all possible intervals and determining the optimal burst order.

Space & Time

Dynamic Programming - LeetMastery - By Patterns

— 2712 —

LeetMastery

Time Complexity: $O(n^3)$ - Three nested loops: one for the interval length, one for the starting index, and one for the final balloon choice.
Space Complexity: $O(n^2)$ - A 2D dynamic programming table is used to store the maximum coins for each interval.

Solution

The problem is solved using interval dynamic programming. First, extend the input array by adding 1 at both ends to handle edge cases seamlessly. Define a dp table where $dp[i][j]$ represents the maximum coins that can be obtained by bursting all the balloons between i and j (not including i and j , as these are the virtual boundaries). For every interval $[i, j]$, iterate through the possible choices for the last balloon k to burst in that interval. The value for bursting balloon k will be determined by the coins from bursting it last (i.e., $nums[i] * nums[k] * nums[j]$) plus the maximum coins from the two resulting subintervals: $[i, k]$ and $[k, j]$. By filling the dp table in increasing interval lengths, you build up to the solution for the overall interval that covers the entire (extended) array.

#1000 Minimum Cost to Merge Stones [Hard]

Key Insights

- You can only merge stones into one final pile if $(n - 1)$ is divisible by $(k - 1)$. If not, return -1 .
- A dynamic programming approach is used where $dp[i][j]$ represents the minimum cost to merge the subarray $stones[i..j]$ into as few piles as possible.
- A prefix sum array is precomputed to quickly calculate the sum of stones in any subarray.
- When a segment can be merged into one pile (i.e. when $(length - 1) \% (k - 1) == 0$), add the sum of stones in that segment to the dp value.

Space & Time

Time Complexity: $O(n^3)$ due to the triple nested loop over segments and splits.

Space Complexity: $O(n^2)$ from the dp table and $O(n)$ for the prefix sum array.

Solution

The problem is solved using a range DP approach. We first verify that merging all piles into one is feasible by checking if $(n - 1) \% (k - 1) == 0$. Next, a prefix sum array is computed to optimize range sum calculations. A 2D dp table $dp[i][j]$ is then used to store the minimum cost to merge $stones[i..j]$. For each interval, we consider valid split points, updating $dp[i][j]$ by combining sub-problems. If the current segment can form a single merged pile (determined by the condition on the interval length), the cost of merging that segment (the sum of stones) is added to $dp[i][j]$.

```
def isValid(s: str) -> bool:
    # Popping from closing brackets to their corresponding opening brackets.
    paren_map = {'(': ')', '[': ']', '{': '}', '<': '>' }
    # Initialize an empty list to use as a stack.
    stack = []

LeetCode · SimplifyLogic · WalleCC · LeetCode · Editorial

String · Stack

Lists · Grid · 169

Problem:

Given a string s containing just the characters '(', ')', '{', '}', '[' and ']', determine if the input string is valid.

An input string is valid if:

1. Open brackets must be closed by the same type of brackets.
2. Open brackets must be closed in the correct order.
3. Every close bracket has a corresponding open bracket of the same type.

Example 1:

Input: $s = "()"$

Output: true

Example 2:

Input: $s = "([)]"$

Output: true

Example 3:

Input: $s = "(]"$

Output: false

Example 4:

Input: $s = "[]"$

Output: true

Example 5:

Input: $s = "[]"$

Output: false

Constraints:

- $1 \leq s.length \leq 104$
- s consists of parentheses only '()[]{}'.

            # For opening brackets, push onto the stack.
            stack.append(char)
    # Return True if all brackets are matched (i.e., the stack is empty).
    return not stack

# Example usage
print(isValid("(){}[]")) # Expected output: True
```

#232 EASY
Implement Queue using Stacks
LeetCode · SimplifyLeet · WalkCC · LeetCode · Editorial
Stack · Design · Queue
List: Grid 129
Problem:
Implement a first in first out (FIFO) queue using only two stacks. The implemented queue should support all the functions of a normal queue (push, peek, pop, and empty).
Implement the MyQueue class:
• void push(int x) Pushes element x to the back of the queue.
• int pop() Removes the element from the front of the queue and returns it.
• int peek() Returns the element at the front of the queue.
• boolean empty() Returns true if the queue is empty, false otherwise.
Notes:
• You must use only standard operations of a stack, which means only push to top, peek/pop from top, size, and is empty operations are valid.
• Depending on your language, the stack may not be supported natively. You may simulate a stack using a list or deque (double-ended queue) as long as you use only a stack's standard operations.
Example 1:
Input
["MyQueue", "push", "push", "peek", "pop", "empty"]
[[1], [2], [1], [1], [1]]
Output

Stack · LeetCode — By Pattern — 2723 — LeetCode

```
[null, null, null, 1, 1, false]
```

Explanation
MyQueue myQueue = new MyQueue();
myQueue.push(1); // queue is: [1]
myQueue.push(2); // queue is: [1, 2] (leftmost is front of the queue)
myQueue.peek(); // return 1
myQueue.pop(); // return 1, queue is [2]
myQueue.empty(); // return false

Constraints:
• 1 <= x <= 9
• At most 100 calls will be made to push, pop, peek, and empty.
• All the calls to pop and peek are valid.
Follow-up: Can you implement the queue such that each operation is amortized O(1) time complexity? In other words, performing n operations will take overall O(n) time even if one of those operations may take longer.

Python
Python
class MyQueue:
 def __init__(self):
 # Stack for enqueue operations.
 self.input_stack = []
 # Stack for dequeue operations.
 self.output_stack = []

 def push(self, x: int) -> None:
 # Always push new elements onto the input stack.
 self.input_stack.append(x)

 def pop(self) -> int:
 # Ensure the output stack has the current queue order.
 if not self.output_stack:
 while self.input_stack:
 # Move all elements from input stack to output stack.
 self.output_stack.append(self.input_stack.pop())
 # The top element of output stack is the front of the queue.
 return self.output_stack.pop()

 def peek(self) -> int:
 # Ensure the output stack has the current queue order.
 if not self.output_stack:
 while self.input_stack:
 # Move all elements from input_stack to output_stack.
 self.output_stack.append(self.input_stack.pop())
 # Peek the top of output stack without popping.
 return self.output_stack[-1]

 def empty(self) -> bool:
 # The queue is empty if both stacks are empty.
 return not self.input_stack and not self.output_stack

Backspace String Compare

LeetCode · SimplyLeet · WalkCCC · LeetCode · Editorial

Two Pointers · String · Stack · Simulation

Ulid Grid 169

Problems

Stack · LeetCode — By Pattern

— 2736 —

LeetCode

Given two strings s and t, return true if they are equal when both are typed into empty text editors. 'a' means a backspace character.

Note that after backspacing an empty text, the text will continue empty.

Example 1:

Input: s = "ab#c", t = "ad#c"
Output: true
Explanation: Both s and t become "ac".

Example 2:

Input: s = "ab##", t = "c#d#"
Output: true
Explanation: Both s and t become "".

Example 3:

Input: s = "a#c", t = "b"
Output: false
Explanation: s becomes "c" while t becomes "b".

Constraints:

- 1 <= s.length, t.length <= 200
- s and t only contain lowercase letters and '#' characters.

Follow up: Can you solve it in O(n) time and O(1) space?

```
Python
# Problem 10. Compare two strings with backspace processing
def backspaceCompare(s: str, t: str) -> bool:
    # Pointers for both strings starting at the end
    i, j = len(s) - 1, len(t) - 1

    # Process both strings until all characters are compared
    while i >= 0 or j >= 0:
        # Process string s: skip backspaced characters
        skip = 0
        while i >= 0:
            if s[i] == '#':
                skip += 1
                i -= 1
            elif skip > 0:
                skip -= 1
                i -= 1
            else:
                break
        # Process string t: skip backspaced characters
        skip = 0
        while j >= 0:
            if t[j] == '#':
                skip += 1
                j -= 1

Reorder List

LeetCode · SimplyList · WUJCC · LeetCode · Editorial
Linked List · Two Pointers · Stack · Recursion

Like · 610 · 100

Problem:

You are given the head of a singly linked-list. The list can be represented as:

$L_0 \rightarrow L_1 \rightarrow \dots \rightarrow L_n - 1 \rightarrow L_n$

Reorder the list to be on the following form:

$L_0 \rightarrow L_n \rightarrow L_1 \rightarrow L_{n-1} \rightarrow L_2 \rightarrow L_{n-2} \rightarrow \dots$

You may not modify the values in the list's nodes. Only nodes themselves may be changed.

Example 1:

Input: head = [1,2,3,4]
Output: [1,4,2,3]

Example 2:

Stack · LeetCode — By Pattern

— 2745 —

LeetCode

Input: head = [1,2,3,4,5]
Output: [1,5,2,4,3]

Constraints:

- The number of nodes in the list is in the range [1, 5 * 10⁴].
- 1 <= Node.val <= 1000

Python

Python

```

Evaluate Reverse Polish Notation

LeetCode · SimpleList · NumCC · LeetCode · Editorial

Array · Math · Stack

List: Grind 169

Problem:

You are given an array of strings tokens that represents an arithmetic expression in a Reverse Polish Notation.

Stack · LeetCode — By Pattern

— 2760 —

LeetCode

Evaluate the expression. Return an integer that represents the value of the expression.

Note that:

- The valid operators are '+', '-', '*', and '/'.
- Each operand may be an integer or another expression.
- The division between two integers always truncates toward zero.
- There will not be any division by zero.
- The input represents a valid arithmetic expression in a reverse polish notation.
- The answer and all the intermediate calculations can be represented in a 32-bit integer.

Example 1:

Input: tokens = ["2","3","+","4","+"]

Output: 9

Explanation: ((2 + 3) + 4) = 9

Example 2:

Input: tokens = ["4","13","3","+","11","*","3","*","+"]

Output: 6

Explanation: (4 + (13 / 3)) = 6

Example 3:

Input: tokens = ["18","6","0","9","3","+","11","*","2","*","13","*","+","5","+"]

Output: 22

Explanation: ((18 + (6 / ((9 + 3) * -11))) + 17) + 5

= ((18 + (6 / (12 * -11))) + 17) + 5

= ((18 + (6 / -132)) + 17) + 5

= ((18 + 0) + 17) + 5

= (0 + 17) + 5

= 17 + 5

= 22

Constraints:

- 1 <= tokens.length <= 104
- tokens[i] is either an operator "+", "-", "*", "/", or an integer in the range [-200, 200].

Min Stack

LeetCode · Simplify · WalkCC · LeetCode · Editorial

Stack · Design

Lists Grid 169

Problem:

Design a stack that supports push, pop, top, and retrieving the minimum element in constant time.

Implement the MinStack class:

- `MinStack()` initializes the stack object.
- `void push(int val)` pushes the element `val` onto the stack.
- `void pop()` removes the element on the top of the stack.
- `int top()` gets the top element of the stack.
- `int getMin()` retrieves the minimum element in the stack.

You must implement a solution with $O(1)$ time complexity for each function.

Example 1:

```
Input
["MinStack","push","push","push","getMin","pop","top","getMin"]
[[],[-2],[1],[-3],[2],[1],[],[1]]
```

Stack · LeetCode — By Pattern

— 2772 —

LeetCode

```
[1,1,-2],[0],[-3],[1],[1],[1]]

Output
[mult,mult,mult,mult,-3,mult,0,-2]
```

Explanation

```
MinStack minStack = new MinStack();
minStack.push(-2);
minStack.push(0);
minStack.push(-3);
minStack.getMin(); // return -3
minStack.pop();
minStack.top(); // return 0
minStack.getMin(); // return -2
```

Constraints:

- $-231 \leq \text{val} \leq 231 - 1$
- Methods pop, top and getMin operations will always be called on non-empty stacks.
- At most $3 * 10^4$ calls will be made to push, pop, top, and getMin.

Python

```
# Python implementation of MinStack with detailed comments

class MinStack:
    def __init__(self):
        # MinStack class to store all values
        self.stack = []
        # Auxiliary stack to store minimum values
        self.min_stack = []

    def push(self, val: int) -> None:
        # Push value into main stack
        self.stack.append(val)
        # If min_stack is empty or the new value is less than or equal to current minimum, push it onto min_stack
        if not self.min_stack or val <= self.min_stack[-1]:
            self.min_stack.append(val)

    def pop(self) -> None:
        # Pop the top value from main stack
        popped_value = self.stack.pop()
        # If the popped value is the current minimum, pop it from min_stack as well
        if popped_value == self.min_stack[-1]:
            self.min_stack.pop()

    def top(self) -> int:
        # Return the top value from main stack without removing it
        return self.stack[-1]

    def getMin(self) -> int:
        # Return the minimum value from min_stack
        return self.min_stack[-1]

# Example usage:
# minStack = MinStack()
# minStack.push(-2)
# minStack.push(-1)
# minStack.push(-3)
# print(minStack.getMin()) # -> -3
# minStack.pop()
# print(minStack.top()) # -> -1
# print(minStack.getMin()) # -> -2
```

Binary Search Tree Iterator

LeetCode · SimplifyLeet · WalkCC · LeetCode · Editorial

Stack · Tree · Design · Binary Search Tree · Recursion

Like · Denny Zhang

Problem:

Implement the BSTIterator class that represents an iterator over the in-order traversal of a binary search tree (BST):

- BSTIterator(TreeNode root) initializes an object of the BSTIterator class. The root of the BST is given as part of the constructor. The pointer should be initialized to a non-existent number

Stack · LeetCode — By Pattern

— 2789 —

LeetCode

- smaller than any element in the BST.
- boolean hasNext() Returns true if there exists a number in the traversal to the right of the pointer, otherwise returns false.
- int next() Moves the pointer to the right, then returns the number at the pointer.

Notice that by initializing the pointer to a non-existent smallest number, the first call to next() will return the smallest element in the BST.

You may assume that next() calls will always be valid. That is, there will be at least a next number in the in-order traversal when next() is called.

Example 1:

```
Input:
["BSTIterator", "next", "next", "hasNext", "next", "hasNext", "next", "hasNext"]
[[7, 3, 15, null, null, 9, 20]], [], [], [], [], [], [], [], []]
Output:
[null, 3, 7, true, 9, true, 15, true, 20, false]
```

Explanation

BSTIterator bSTIterator = new BSTIterator([7, 3, 15, null, null, 9, 20]);

bSTIterator.next(); // return 3

bSTIterator.next(); // return 7

bSTIterator.hasNext(); // return True

bSTIterator.next(); // return 9

bSTIterator.hasNext(); // return True

bSTIterator.next(); // return 15

bSTIterator.hasNext(); // return True

bSTIterator.next(); // return 20

bSTIterator.hasNext(); // return False

Constraints:

- The number of nodes in the tree is in the range [1, 105].
- 0 <= Node.val <= 106
- At most 105 calls will be made to hasNext, and next.

Follow up:

Stack · LeetCode — By Pattern

— 2790 —

LeetCode

• Could you implement next() and hasNext() to run in average O(1) time and use O(h) memory, where h is the height of the tree?

Python

```
Python
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right

class BSTIterator:
    def __init__(self, root):
        # Initialize an empty stack to simulate in-order traversal
        self.stack = []
        # Push all left nodes starting from the root
        self._push_left_branch(root)

    def _push_left_branch(self, node):
        # Push node and all its left children to the stack
        while node:
            self.stack.append(node)
            node = node.left

    def next(self):
        # Pop the top node which represents the next smallest element
        node = self.stack.pop()
        # If the node has a right child, push its left branch onto the stack
        if node.right:
            self._push_left_branch(node.right)
        # Return the node's value
        return node.val

    def hasNext(self):
        # The iterator has a next element if the stack is not empty
        return len(self.stack) > 0
```

Math · String · Stack

Like · 100

Problem:
Given a string *s* which represents an expression, evaluate this expression and return its value.
The integer division should truncate toward zero.
You may assume that the given expression is always valid. All intermediate results will be in the range of $[-2^{31}, 2^{31} - 1]$.

Note: You are not allowed to use any built-in function which evaluates strings as mathematical expressions, such as `eval()`.

Example 1:
Input: *s* = "3+2*2"
Output: 7

Example 2:
Input: *s* = " 3/2 "
Output: 1

Example 3:
Input: *s* = " 3*5 / 2 "
Output: 5

Constraints:

- $1 \leq s.length \leq 3 \times 10^5$
- s* consists of integers and operators `('+', '-', '*', '/')` separated by some number of spaces.
- s* represents a valid expression.
- All the integers in the expression are non-negative integers in the range $[0, 2^{31} - 1]$.
- The answer is guaranteed to fit in a 32-bit integer.

Verify Preorder Sequence in Binary Search Tree

LeetCode · Interview · Basic · LeetCode · Editorial

Array · Tree · BST · Stack · Monotonic Stack

Like Premium 98

Problem:

Given an array of unique integers preorder, return true if it is the correct preorder traversal sequence of a binary search tree.

Example 1:

Input: preorder = [5,2,1,3,6]
Output: true

Example 2:

Input: preorder = [5,2,6,1,3]
Output: false

Constraints:

- 1 <= preorder.length <= 104
- 1 <= preorder[i] <= 104

- All the elements of preorder are unique.

Follow up: Could you do it using only constant space complexity?

Decode String

LeetCode · SimplifyLeetCode · WubCC · LeetCode · Editorial

String · Stack · Recursion

Like · 619 · Dislike · 169

Problem:

Given an encoded string, return its decoded string.

The encoding rule is: $k[\text{encoded_string}]$, where the encoded_string inside the square brackets is being repeated exactly k times. Note that k is guaranteed to be a positive integer.

You may assume that the input string is always valid; there are no extra white spaces, square brackets are well-formed, etc. Furthermore, you may assume that the original data does not contain any digits and that digits are only for those repeat numbers, k . For example, there will not be input like $3a$ or $2[4]$.

The test cases are generated so that the length of the output will never exceed 105.

Example 1:

Input: $s = "3[a]2[b]c"$

Output: "aaabcbcc"

Example 2:

Input: $s = "3[a]c[1]"$

Output: "accaccacc"

Example 3:

Input: $s = "2[abc]3[cd]ef"$

Output: "abccabcccdccdef"

Constraints:

- $1 \leq s.length \leq 30$
- s consists of lowercase English letters, digits, and square brackets $[]$.
- s is guaranteed to be a valid input.
- All the integers in s are in the range $[1, 300]$.

Python

```

def decodeString(s: str) -> str:
    # Index pointer as a list so it can be mutable within recursion
    def helper(i: int) -> (str, int):
        decoded = ""
        while i < len(s):
            if s[i].isdigit():
                # Build the number (it might be more than one digit)
                k = 0
                while i < len(s) and s[i].isdigit():
                    k = k * 10 + int(s[i])
                    i += 1
                # Skip the '[' character
                i += 1
                # Recursively solve the substring inside the brackets
                sub, i = helper(i)
                # Repeat the substring repeated k times
                decoded += sub * k
            elif s[i] == '[':
                # Return the decoded string and new index after '['
                return decoded, i + 1
            else:
                # Accumulate alphabetic characters directly
                decoded += s[i]
                i += 1

Ternary Expression Parser

LeetCode · [Simple](#) · [LeetCode](#) · [WahCCE](#) · [LeetCode](#) · [Editorial](#)

String · Stack · Recursion

List: Premium 98

Problem:

Given a string expression representing arbitrarily nested ternary expressions, evaluate the expression, and return the result of it.

You can always assume that the given expression is valid and only contains digits, 'T', 'F', 'I', and '?' where 'T' is true and 'F' is false. All the numbers in the expression are one-digit numbers (i.e., in the range [0, 9]).

The conditional expressions group right-to-left (as usual in most languages), and the result of the expression will always evaluate to either a digit, 'T' or 'F'.

Example 1:

Input: expression = "T?T?F:5:3"

Output: "2"

Explanation: If true, then result is 2; otherwise result is 3.

Example 2:

Input: expression = "FT?T?T4:5"

Output: "4"

Explanation: The conditional expressions group right-to-left. Using parenthesis, it is read/evaluated as:

"(F ? 1 : (T ? 4 : 5))" ==> "(F ? 1 : 4)" ==> "4"

or "(F ? 1 : (T ? 4 : 5))" ==> "(T ? 4 : 5)" ==> "4"

Example 3:

Input: expression = "T?T?F:5:3"

Output: "2"

Explanation: The conditional expressions group right-to-left. Using parenthesis, it is read/evaluated as:

"(F ? (T ? T : 5) : 3)" ==> "(T ? T : 3)" ==> "3"

"(T ? (T ? T : 5) : 3)" ==> "(T ? T : 5)" ==> "5"

Constraints:

- 5 <= expression.length <= 104
- expression consists of digits, 'T', 'F', 'I', and '?'.
- It is guaranteed that expression is a valid ternary expression and that each number is a one-digit number.

Python

```
def parseTernary(expression: str) -> str:
    # Initialize stack to hold characters/results during evaluation
    stack = []
    # Iterate backwards over the expression
    i = len(expression) - 1
    while i >= 0:
        if expression[i] == 'T':
            # Pop the true and false parts from the stack
            true_expr = stack.pop()
            false_expr = stack.pop()
            i -= 1 # Move to the condition character
            # Check based on the condition
            if expression[i] == 'T':
                stack.append(true_expr)
            else:
                stack.append(false_expr)
        elif expression[i] == '?':
            # Skip the colon as it is only a separator
            pass
        else:
            # One digit, 'F', and 'I' onto stack as is
            stack.append(expression[i])
            i -= 1 # Move to the next character

Find Permutation

LeetCode · Solution · WalkCC · LeetCode · Editorial

Array · String · Stack · Greedy

List: Premium 98

Problem:

A permutation perm of n integers of all the integers in the range [1, n] can be represented as a string s of length n - 1 where:

• s[i] = 'I' if perm[i] < perm[i + 1], and

• s[i] = 'D' if perm[i] > perm[i + 1].

Given a string s, reconstruct the lexicographically smallest permutation perm and return it.

Example 1:

Input: s = "I"

Output: [1,2]

Explanation: [1,2] is the only legal permutation that can be represented by s, where the number 1 and 2 construct an increasing relationship.

Example 2:

Input: s = "DI"

Output: [2,1,3]

Explanation: Both [2,1,3] and [3,1,2] can be represented as "DI", but since we want to find the smallest lexicographical permutation, you should return [2,1,3]

Constraints:

• 1 <= s.length <= 105

• s[i] is either 'I' or 'D'.

#735 MEDIUM Asteroid Collision

LeetCode · Simplest · MathCC · LeetCode · Editorial

Array · Stack · Simulation

List · Grid 189

Problem:

We are given an array asteroids of integers representing asteroids in a row. The indices of the asteroid in the array represent their relative position in space.

For each asteroid, the absolute value represents its size, and the sign represents its direction (positive meaning right, negative meaning left). Each asteroid moves at the same speed.

Find out the state of the asteroids after all collisions. If two asteroids meet, the smaller one will explode. If both are the same size, both will explode. Two asteroids moving in the same direction will never meet.

Example 1:

Input: asteroids = [5,10,-5]

Output: [5,10]

Explanation: The 10 and -5 collide resulting in 10. The 5 and 10 never collide.

Example 2:

Input: asteroids = [8,-8]

Output: []

Explanation: The 8 and -8 collide exploding each other.

Example 3:

Input: asteroids = [10,2,-5]

Output: [10]

Explanation: The 2 and -5 collide resulting in -5. The 10 and -5 collide resulting in 10.

Example 4:

Input: asteroids = [3,5,-6,2,-1,4]

Output: [-6,2,4]

Stack · LeetCode — By Pattern — 2843 — LeetCode

Explanation: The asteroid -6 makes the asteroid 3 and 5 explode, and then continues going left. On the other side, the asteroid 2 makes the asteroid -1 explode and then continues going right, without reaching asteroid 4.

Constraints:

• 2 <= asteroids.length <= 104

• -1000 <= asteroids[i] <= 1000

• asteroids[0] != 0

# Function to simulate asteroid collisions
def asteroidCollision(asteroids):
    # Initialize an empty list as a stack to hold surviving asteroids
    stack = []
    # Iterate through each asteroid in the input list
    for ast in asteroids:
        # Flag to check if the current asteroid has exploded
        exploded = False
        # Check for potential collision while there is an asteroid in stack and a collision condition holds
        # (right-moving on stack and left-moving current)
        while stack and ast < 0 and stack[-1] > 0:
            # If the incoming left-moving asteroid is larger than the right-moving one on stack, pop the
            # top and continue checking
            if abs(ast) > abs(stack[-1]):
                stack.pop()
            # Continue the loop to check next potential collision
            # If they are equal, both explode: pop the stack and mark explosion, break the loop
            elif abs(ast) == abs(stack[-1]):
                stack.pop()
            # Mark the incoming asteroid as exploded and break out of the loop
            exploded = True
            break
        # If the asteroid did not explode during collisions, push it onto the stack
        if not exploded:
            stack.append(ast)
    # Return the surviving asteroids
    return stack

```

Example usage:
print(asteroidCollision([5,10,-5])) # Output: [5,10]

Daily Temperatures

LeetCode · Synopsis · Discuss · Solution · LeetCode · Editorial

Array · Stack · Monotonic Stack

List: Grid 169

Problem:

Given an array of integers temperatures represents the daily temperatures, return an array answer such that answer[i] is the number of days you have to wait after the ith day to get a warmer temperature. If there is no future day for which this is possible, keep answer[i] == 0 instead.

Example 1:

Input: temperatures = [73,74,75,71,69,72,76,73]
Output: [1,1,4,2,1,1,0,0]

Example 2:

Input: temperatures = [30,40,50,60]
Output: [1,1,1,0]

Example 3:

Stack · LeetCode — By Pattern

— 2852 —

LeetCode

Input: temperatures = [30,40,90]
Output: [1,1,0]

Constraints:

• 1 <= temperatures.length <= 105
• 30 <= temperatures[i] <= 100

Maximum Width Ramp
LeetCode · Companies · LeetCode · Editorial
Array · Stack · Monotonic Stack
Like Denny Zhang
Problem:
A ramp in an integer array nums is a pair (i, j) for which i < j and nums[i] <= nums[j]. The width of such a ramp is j - i.
Given an integer array nums, return the maximum width of a ramp in nums. If there is no ramp in nums, return 0.
Example 1:
Input: nums = [6,0,8,2,1,5]
Output: 4
Explanation: The maximum width ramp is achieved at (i, j) = (1, 5): nums[1] = 0 and nums[5] = 5.
Example 2:
Input: nums = [9,8,1,0,1,9,4,0,4,1]
Output: 7
Explanation: The maximum width ramp is achieved at (i, j) = (2, 9): nums[2] = 1 and nums[9] = 1.
Constraints:
• 2 <= nums.length <= 5 * 10⁴
• 0 <= nums[i] <= 5 * 10⁴

Like · Premium

Problem:

Given the roots of two binary search trees, root1 and root2, return true if and only if there is a node in the first tree and a node in the second tree whose values sum up to a given integer target.

Example 1:

9	9	8	1
5	6	2	6
8	2	6	4
6	2	2	2

9	9
8	6

Input: root1 = [2,1,4], root2 = [1,0,3], target = 5
Output: true
Explanation: 2 and 3 sum up to 5.

Example 2:

```
graph TD
    0((0)) --> -10((-10))
    0 --> 10((10))
    10 --> 1((1))
    10 --> 7((7))
    1 --> 0((0))
    1 --> 2((2))
```

Input: root1 = [8,-10,10], root2 = [5,1,7,0,2], target = 18
Output: false
Constraints:
• The number of nodes in each tree is in the range [1, 5000].
• -109 <= Node.val, target <= 109

Python

```
# Definition for a binary tree node.
class TreeNode:
    def __init__(self, val=0, left=None, right=None):
        self.val = val
        self.left = left
        self.right = right

def twoSumBSTs(root1: TreeNode, root2: TreeNode, target: int) -> bool:
    # Create a set to store values from the first BST
    values_set = set()

    # Helper function to perform DFS and add node values to the set.
    def dfs_collect(node):
        if not node:
            return
        values_set.add(node.val) # Add current node value
        dfs_collect(node.left) # Traverse left subtree
        dfs_collect(node.right) # Traverse right subtree

    # Collect all values from first tree.
    dfs_collect(root1)

    # Helper function to traverse second tree and check for complement.
    def dfs_check(node):
        if not node:
            return False

        # If the complement exists in the first tree values, return True.
        if target - node.val in values_set:
            return True

        # Recursively check left and right children.
        return dfs_check(node.left) or dfs_check(node.right)

    # Check the second tree.
    return dfs_check(root2)

# Example usage:
# Construct trees and call twoSumBSTs as needed.
```

Buildings With an Ocean View

LeetCode · Solution · WalkCC · LeetCode · Editorial

Array · Stack · Monotonic Stack

List: Premium 98

Problem:

Stack · LeetCode · By Pattern

— 2878 —

LeetCode

There are n buildings in a line. You are given an integer array `heights` of size n that represents the heights of the buildings in the line.

The ocean is to the right of the buildings. A building has an ocean view if the building can see the ocean without obstructions. Formally, a building has an ocean view if all the buildings to its right have a smaller height.

Return a list of indices (0-indexed) of buildings that have an ocean view, sorted in increasing order.

Example 1:

Input: `heights = [4,2,3,1]`

Output: `[0,2,3]`

Explanation: Building 1 (0-indexed) does not have an ocean view because building 2 is taller.

Example 2:

Input: `heights = [4,3,2,1]`

Output: `[0,1,2,3]`

Explanation: All the buildings have an ocean view.

Example 3:

Input: `heights = [1,3,2,4]`

Output: `[3]`

Explanation: Only building 3 has an ocean view.

Constraints:

- $1 \leq \text{heights.length} \leq 105$
- $1 \leq \text{heights}[i] \leq 109$

#32 **HARD**

Longest Valid Parentheses

LeetCode · Simplify · Waffle · LeetCode · Editorial

String · Dynamic Programming · Stack

Lists · Grid · 169

Problem:

Given a string containing just the characters '(' and ')', return the length of the longest valid (well-formed) parentheses substring.

Example 1:

Input: s = "(()"

Output: 2

Explanation: The longest valid parentheses substring is "()".

Example 2:

Input: s = "()()"

Output: 4

Explanation: The longest valid parentheses substring is "()()".

Example 3:

Input: s = ""

Output: 0

Constraints:

- 0 <= s.length <= 3 * 10⁴
- s[i] is '(' or ')'

```

# Python solution using a stack
def longestValidParentheses(s: str) -> int:
    # Initialize the stack with the base index -1
    stack = [-1]
    max_length = 0

    # Iterate over the string with index
    for i, char in enumerate(s):
        if char == '(':
            # Push the index of '(' onto the stack
            stack.append(i)
        else:
            # Pop the last index for ')'
            stack.pop()
            # If our stack is empty, push current index as the new base
            if not stack:
                stack.append(i)
            # Calculate the length of the current valid substring
            current_length = i - stack[-1]
            max_length = max(max_length, current_length)

    return max_length

# Example usage:
print(longestValidParentheses("()()()")) # Output: 6

```

Python

Trapping Rain Water

LeetCode · Simplest · Medium · LeetCode · Editorial

Array · Two Pointers · Dynamic Programming · Stack · Monotonic Stack

Like: Grind 169

Problem:

Given n non-negative integers representing an elevation map where the width of each bar is 1, compute how much water it can trap after raining.

Example 1:

Stack · LeetCode — By Pattern

— 2898 —

LeetCode

Input: height = [0,1,0,2,1,0,1,3,2,1,2,1]
Output: 6
Explanation: The above elevation map (black section) is represented by array [0,1,0,2,1,0,1,3,2,1,2,1]. In this case, 6 units of rain water (blue section) are being trapped.

Example 2:
Input: height = [4,2,0,3,2,5]
Output: 9

Constraints:

- n == height.length
- 1 <= n <= 2 * 10⁴
- 0 <= height[i] <= 105

Largest Rectangle in Histogram

LeetCode · [SimplyEasi](#) · [WubCC](#) · [LeetCode](#) · [Editorial](#)

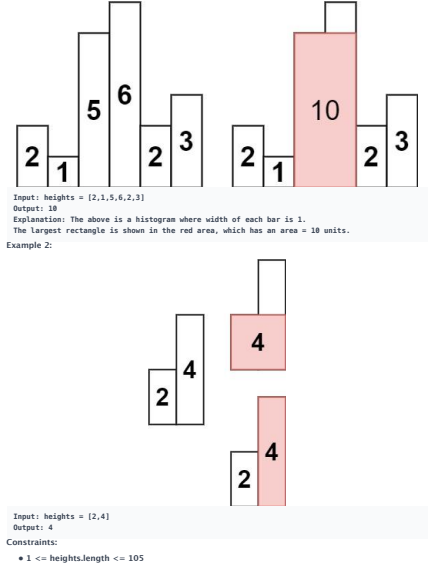

Array · Stack · [Monotonic Stack](#)

Uvic Grid 109

Problem:

Given an array of integers heights representing the histogram's bar height where the width of each bar is 1, return the area of the largest rectangle in the histogram.

Example 1:

```
• 0 <= heights[i] <= 104
```

— 2925 —

LeetCode

Problem:

Given a string `s` representing a valid expression, implement a basic calculator to evaluate it, and return the result of the evaluation.

Note: You are not allowed to use any built-in function which evaluates strings as mathematical expressions, such as `eval()`.

Example 1:

Input: `s = "1 + 1"`
Output: `2`

Example 2:

Input: `s = " 2-1 + 2 "`
Output: `3`

Example 3:

Input: `s = "(1+(4+5+2)-3)+(6+8)"`
Output: `23`

Constraints:

- `s` consists of digits, `+`, `-`, `*`, `/`, `"(",` and `)`.
- `s` represents a valid expression.
- `+` is not used as a unary operation (i.e., `++1` and `-(2 + 3)` is invalid).
- `-` could be used as a unary operation (i.e., `-1` and `-(2 + 3)` is valid).
- There will be no two consecutive operators in the input.
- Every number and running calculation will fit in a signed 32-bit integer.

Sliding Window Maximum
[LeetCode](#) • [SimplyEasiest](#) • [WuJCC](#) • [LeetCode](#) • [Editorial](#)
[Array](#) • [Queue](#) • [Sliding Window](#) • [Monotonic Queue](#)
[Listas Grind 189](#)

Problem:
You are given an array of integers nums, there is a sliding window of size k which is moving from the very left of the array to the very right. You can only see the k numbers in the window. Each time the sliding window moves right by one position.
Return the max sliding window.

Example 1:
Input: nums = [1,3,-1,-3,5,3,6,7], k = 3
Output: [3,5,6,7]
Explanation:
Window position Max

[1 3 -1] -> 3 5 6 7 3
1 [3 -1 -3] -> 5 6 7 3
1 3 [-1 -3 5] -> 6 7 5
1 3 -1 [-3 5 3] -> 6 7 5
1 3 -1 -3 [5 3 6] -> 7 6
1 3 -1 -3 5 [6 7] -> 7

Example 2:
Input: nums = [1], k = 1
Output: [1]

Constraints:
• 1 <= nums.length <= 105
• -104 <= nums[i] <= 104
• 1 <= k <= nums.length

Max Stack

LeetCode · SimplifyLeet · WalkCC · LeetCode · Editorial

Stack · Design · Doubly-Linked List · Ordered Set

Little Denny Zhang

Problem:

Design a max stack data structure that supports the stack operations and supports finding the stack's maximum element.

Implement the MaxStack class:

- MaxStack() Initializes the stack object.
- void push(int x) Pushes element x onto the stack.
- int pop() Removes the element on top of the stack and returns it.
- int top() Gets the element on the top of the stack without removing it.
- int peekMax() Retrieves the maximum element in the stack without removing it.
- int popMax() Retrieves the maximum element in the stack and removes it. If there is more than one maximum element, only remove the top-most one.

You must come up with a solution that supports O(1) for each top call and O(logn) for each other call.

Example 1:

```
Input
["MaxStack", "push", "push", "push", "top", "popMax", "top", "peekMax", "pop", "top"]
[[], [5], [2], [5], [1, 1, 1, 1, 1, 1, 1]]
Output
[null, null, null, null, 5, 5, 1, 5, 1, 5]
```

Explanation

```
MaxStack stk = new MaxStack();
stk.push(5); // [5] the top of the stack and the maximum number is 5.
stk.push(1); // [5, 1] the top of the stack is 1, but the maximum is 5.
stk.push(2); // [5, 1, 2] the top of the stack is 2, which is also the maximum, because it is the top most one.
stk.top(); // return 2, [5, 1, 2] the stack did not change.
stk.popMax(); // return 5, [5, 1] the stack is changed now, and the top is different from the max.
stk.top(); // return 1, [5, 1] the stack did not change.
stk.peekMax(); // return 5, [5, 1] the stack did not change.
stk.pop(); // return 1, [5] the top of the stack and the max element is now 5.
stk.top(); // return 5, [5] the stack did not change.
```

Constraints:

- -107 <= x <= 107
- At most 105 calls will be made to push, pop, top, peekMax, and popMax.
- There will be at least one element in the stack when pop, top, peekMax, or popMax is called.

Python

Python

```
# Python solution implementing the MaxStack data structure
# we use collections.deque for deque operation
# However, in Python we do not have a built-in balanced BST,
# one can use "sortedcontainers" or manually maintain a heap and dictionary.
# For clarity, we illustrate an approach using only a heap and dictionary.
# In production, one may use "sorteddict" from sortedcontainers.

from collections import defaultdict

class Node:
    def __init__(self, val):
        self.val = val
        self.prev = None
        self.next = None

Basic Calculator III

LeetCode · Simple · Math · Recursion · Editorial

Math · String · Stack · Recursion

List: Premium 98

Problem:

Implement a basic calculator to evaluate a simple expression string.

The expression string contains only non-negative integers, '+', '-', '*', '/', parentheses, and open '(' and closing parentheses ')'. The integer division should truncate toward zero.

You may assume that the given expression is always valid. All intermediate results will be in the range of [-2³¹, 2³¹ - 1].

Note: You are not allowed to use any built-in function which evaluates strings as mathematical expressions, such as eval().

Example 1:

Input: s = "1+1"

Output: 2

Example 2:

Input: s = "6+4/2"

Output: 4

Example 3:

Input: s = "2+(5+5*2)/(6/2+8)"

Output: 21

Constraints:

- 1 <= s.length <= 10⁴
- s consists of digits, '+', '-', '*', '/', '(', ')', and space.
- s is a valid expression.

Python

```

def calculate(s: str) -> int:
    # Recursive helper function that processes the expression starting from index 0
    def helper(i):
        stack = []
        num = 0
        sign = '+'
        while i < len(s):
            char = s[i]
            # Build the current number if the character is a digit
            if char.isdigit():
                num = num * 10 + int(char)
            # If it is an operator or closing parenthesis, process the sign and number
            if char in '+-*/' or char == ')':
                if char == '(':
                    num, i = helper(i + 1)
                # Now we have a number, an operator or closing parenthesis, process the sign and number
                if (not char.isdigit() and char != '(') or i == len(s) - 1:
                    if sign == '+':
                        stack.append(num)
                    elif sign == '-':

HARD

Maximum Frequency Stack

LeetCode · SimplifyStack · MultiCC · LeetCode · Editorial

Hash Table · Stack · Design

Lists Grind 169

Problem:

Design a stack-like data structure to push elements to the stack and pop the most frequent element from the stack.

Implement the FreqStack class:

- FreqStack() constructs an empty frequency stack.
- void push(int val) pushes an integer val onto the top of the stack.

Stack · LeetCodeMastery — By Pattern

— 2966 —

LeetCodeMastery

- int pop() removes and returns the most frequent element in the stack. If there is a tie for the most frequent element, the element closest to the stack's top is removed and returned.

Example 1:

```

Input
["FreqStack", "push", "push", "push", "push", "push", "pop", "pop", "pop", "pop"]
[[], [5], [7], [5], [7], [4], [5], [1], [1], [1], [1]]
Output
[null, null, null, null, null, null, 5, 7, 5, 4]

```

Explanation
 FreqStack freqStack = new FreqStack();
 freqStack.push(5); // The stack is [5]
 freqStack.push(7); // The stack is [5,7]
 freqStack.push(5); // The stack is [5,7,5]
 freqStack.push(7); // The stack is [5,7,5,7]
 freqStack.push(4); // The stack is [5,7,5,7,4]
 freqStack.push(); // The stack is [5,7,5,7,4,5]
 freqStack.pop(); // return 5, as 5 is the most frequent. The stack becomes [5,7,5,7,4].
 freqStack.pop(); // return 7, as 5 and 7 is the most frequent, but 7 is closest to the top.
 The stack becomes [5,7,5,4].
 freqStack.pop(); // return 5, as 5 is the most frequent. The stack becomes [5,7,4].
 freqStack.pop(); // return 4, as 4, 5 and 7 is the most frequent, but 4 is closest to the top. The stack becomes [5,7].

Constraints:

- 0 <= val <= 100
- At most 2 * 10⁴ calls will be made to push and pop.
- It is guaranteed that there will be at least one element in the stack before calling pop.

        group[f].push_back(val);
    }

    // Pop method
    int pop() {
        // Get the most frequent element from the top of the stack for max frequency

        int val = group[maxFreq].back();
        group[maxFreq].pop_back();
        // Decrease the frequency count of the popped value
        freq[val]--;
        // If this group is now empty, decrease the max frequency count
        if (group[maxFreq].empty())
            maxFreq--;
        return val;
    }

private:
    // Mapping from value to frequency count
    unordered_map<int, int> freq;
    // Mapping from frequency to a vector (acting as a stack) of values
    unordered_map<int, vector<int>> group;
    // Current maximum frequency in the stack
    int maxFreq;
};

```

Python

Quick Review — Stack 25 questions · insights · complexity · solution

#20 Valid Parentheses [Easy]

Key Insights

- The problem can be solved using a stack data structure.
- When encountering an opening bracket, push it onto the stack.
- When encountering a closing bracket, check if the top of the stack is its matching opening bracket.
- If the stack is empty before finding a match or if there is a mismatch, the string is invalid.
- At the end, the string is valid only if the stack is empty, meaning all brackets were properly matched.

Space & Time

Time Complexity: $O(n)$, where n is the length of the string, since we process each character once.
Space Complexity: $O(n)$ in the worst case for the stack when all characters are opening brackets.

Solution

We use a stack to check for valid parentheses. The algorithm iterates through the string, pushing opening brackets onto the stack and popping them when a corresponding closing bracket is encountered. A mapping of closing to opening brackets helps in validating the matching pairs. By ensuring that the stack is empty at the end, we confirm that every opening bracket was properly closed.

#232 Implement Queue using Stacks [Easy]

Key Insights

- Use two stacks:
- One (input stack) for enqueue operations.
- The other (output stack) for dequeue operations.
- When performing pop or peek, if the output stack is empty, transfer all elements from the input stack to the output stack. This reversal makes the oldest element accessible.
- Each element is moved at most once between the stacks, ensuring an amortized $O(1)$ cost per operation.
- The space complexity is $O(n)$ where n is the number of elements in the queue.

Space & Time

Time Complexity: Amortized $O(1)$ per operation
Space Complexity: $O(n)$

Solution

We maintain two stacks: an input stack for pushing new elements and an output stack for popping or peeking the front element of the queue. When we need to access the front of the queue (either during a pop or peek), we check if the output stack is empty. If it is, we transfer all elements from the input stack to the output stack. This reversal of order allows us to simulate the FIFO nature of the queue. When performing a push, the element is simply added to the input stack.

#844 Backspace String Compare [Easy]

Key Insights

- '#' represents a backspace operation that deletes the previous character.
- A direct simulation using a stack can reconstruct the final string.
- A two-pointer approach allows comparison from the end of the strings while skipping backspace characters.
- The two-pointer technique can achieve $O(n)$ time and $O(1)$ space by processing the strings in reverse.

Space & Time

Stack · LeetCodeMastery — By Pattern

— 297 —

LeetCodeMastery

- A common approach is to use two stacks: one regular stack for all elements and a second stack to keep track of the minimum values.
- When pushing a new element, push it onto the main stack and also update the min stack if the element is less than or equal to the current minimum.
- When popping, if the popped element is equal to the top of the min stack, pop from the min stack as well.
- This design guarantees that all operations (push, pop, top, getMin) run in constant time, $O(1)$.

Space & Time

Time Complexity: $O(1)$ per operation (push, pop, top, getMin)
Space Complexity: $O(n)$, where n is the number of elements in the stack, since an additional stack is used to keep track of minima.

Solution

The solution involves using two stacks:

- Main Stack: Stores all the elements.
- Min Stack: Stores the minimum elements encountered so far.

When an element is pushed, we compare it with the top of the min stack. If it is smaller than or equal to the current minimum, we also push it onto the min stack. For the pop operation, if the element being popped is the same as the top of the min stack, we pop from the min stack as well. This approach ensures that the getMin operation always returns the top element of the min stack, which is the current minimum in constant time.

#173 Binary Search Tree Iterator [Medium]

Key Insights

- Use an iterative in-order traversal strategy with a stack.
- In-order traversal for BST yields sorted order.
- Pre-load the stack with all left descendants from the root.
- After returning a node, process its right subtree by pushing its left branch.
- This method maintains an average time complexity of $O(1)$ per operation and uses $O(h)$ memory, where h is the tree height.

Space & Time

Time Complexity: $O(1)$ on average per operation (amortized)
Space Complexity: $O(h)$, where h is the height of the tree

Solution

We use a stack to simulate an in-order traversal. The process involves initially pushing all left-child nodes from the root into the stack. For each call to next(), we pop the top element (the current smallest node) and then push all the left descendants of the node's right child. This ensures that the next smallest element is always at the top of the stack. The hasNext() function then simply checks if the stack is non-empty.

#227 Basic Calculator II [Medium]

Key Insights

- The expression can be processed in one pass while using a stack to handle operator precedence.
- When encountering '*' or '/' operators, the current number is directly added or subtracted (as a positive or negative value).
- For '+' and '-' operators, compute immediately with the last number from the stack and update it.
- Handle spaces and multi-digit numbers by building the number while iterating over the string.
- Division truncation toward zero must be carefully applied, which aligns with typical integer division in most languages.

Space & Time

Time Complexity: $O(n)$ where n is the length of the expression, since the algorithm processes each character once.
Space Complexity: $O(n)$ in the worst-case scenario when all numbers are stored in the stack.

Stack · LeetCodeMastery — By Pattern

LeetCodeMastery

#439 Ternary Expression Parser [Medium]

Key Insights

- The ternary operator groups right-to-left. This property can be exploited by processing the string from the end to the beginning.
- Using a stack allows us to "collapse" nested ternary expressions as soon as their three components (condition, true branch, false branch) are available.
- An iterative approach is efficient and avoids building an explicit syntax tree for the expression.
- The condition is not stored on the stack; instead, it is encountered immediately preceding the '?' operator when traversing backwards.

Space & Time

Time Complexity: $O(n)$, where n is the length of the expression, as we process each character exactly once.
Space Complexity: $O(n)$, due to the use of a stack for storing characters during evaluation.

Solution

The solution uses an iterative approach with a stack. We traverse the expression string from right to left. For every character:

- If it is a digit, 'T', or 'F' (and not a '?' or part of a pending operator), we push it onto the stack.
- When we encounter a '?' character, we know that the next available items on the stack represent the true and false results of the ternary expression. We then skip the ':' separator that comes between them.
- We then use the condition (the character immediately preceding the '?') to choose which result to push back on the stack. This method "collapses" each ternary expression into a single result, and by the time we finish traversing the string, the stack contains the final evaluated result.

#484 Find Permutation [Medium]

Key Insights

- The answer is a permutation of numbers from 1 to n , where $n = \text{len}(s) + 1$.
- A common strategy is to use a stack to reverse the segments when a decrease (D) is encountered.
- When an 'I' is encountered (or at the end), pop all numbers from the stack to output them in reverse order, ensuring the smallest lexicographical order.
- This greedy approach guarantees that as soon as a rising pattern is detected, we "flush" the pending decreases correctly.

Space & Time

Time Complexity: $O(n)$ · Each element is pushed and popped exactly once.
Space Complexity: $O(n)$ · For the stack and the output array.

Solution

We use a greedy approach with a stack. Iterate from 0 to n (where $n = \text{len}(s) + 1$):

- Push the current number ($i+1$) onto the stack.
- If the current character is 'I' or we have reached the end of the string, pop all elements from the stack and append them to the result.
- By doing so, segments corresponding to series of 'D's are reversed, while 'I's trigger the flush, ensuring that the final permutation is the lexicographically smallest.

#735 Asteroid Collision [Medium]

Key Insights

- Use a stack to keep track of the surviving asteroids.
- Only a collision happens when a right-moving asteroid (positive) is on the stack and a left-moving asteroid (negative) is encountered.
- Compare the absolute values to decide if one or both asteroids explode.
- Continue processing collisions until no further collisions are possible with the current asteroid.

Space & Time

Stack · LeetCodeMastery — By Pattern

— 2981 —

LeetCodeMastery

Time Complexity: $O(n)$ where n is the length of the longer string.

Space Complexity: $O(1)$ using the two-pointer strategy ($O(n)$ if using stacks).

Solution

The solution uses two pointers starting from the end of each string. For each string, maintain a skip counter to account for backspace characters. As you iterate backwards:

- If a '#' is encountered, increment the skip counter.
- If a normal character is encountered while the skip counter is positive, skip that character by decrementing the counter.
- Once a valid character is found, compare the characters from both strings. If all corresponding characters match and both pointers finish processing at the same time, the strings are considered equal.

#143 Reorder List [Medium]

Key Insights

- Find the middle of the linked list using the fast and slow pointer technique.
- Reverse the second half of the list.
- Merge the two halves, alternating nodes from the first half and the reversed second half.
- The challenge is done in-place, ensuring a linear time solution with constant extra space.

Space & Time

Time Complexity: $O(n)$ · Each of the three main steps (finding the middle, reversing, merging) takes $O(n)$ time.
Space Complexity: $O(1)$ · The algorithm is done in-place with only a few pointers.

Solution

The solution involves three key steps:

- Use two pointers (slow and fast) to identify the middle of the list.
- Reverse the second half of the list. This can be done iteratively by adjusting the next pointers.
- Merge the two lists: One starting from the head and the other from the head of the reversed second half. Interleave the nodes by alternating between the two lists until complete. This approach uses in-place pointer manipulation, thus ensuring no extra space is used aside from a few temporary variables.

#150 Evaluate Reverse Polish Notation [Medium]

Key Insights

- Use a stack to process the tokens.
- Push numbers onto the stack.
- When an operator is encountered, pop the top two numbers, perform the operation, and push the result back.
- Handle division carefully to ensure it truncates toward zero.
- The final result remains as the only value in the stack.

Space & Time

Time Complexity: $O(n)$, where n is the number of tokens (each token is processed once).
Space Complexity: $O(n)$, in the worst-case scenario where all tokens are numbers and are stored in the stack.

Solution

We use a stack data structure to evaluate the RPN expression. Iterate through each token:

- If the token is a number, convert and push it onto the stack.
- If the token is an operator, pop the top two numbers (be careful about order), perform the corresponding arithmetic operation, and push the result back onto the stack.
- At the end of processing, the stack contains the result of the expression. Special attention is needed for division to ensure it truncates toward zero (using language-specific functions when necessary).

#155 Min Stack [Medium]

Key Insights

- Use an auxiliary data structure to track the current minimum element.

Stack · LeetCodeMastery — By Pattern

— 2978 —

LeetCodeMastery

Solution

We use a stack-based approach. Iterate over each character of the string while maintaining a variable for the current number and a previous operator (initialized to '+'). When an operator or the end of the string is reached, perform an action based on the previous operator:

- For '+' add the current number to the stack.
- For '-' add the negative of the current number.
- For '*' and '/' pop the last number from the stack, compute the result by performing multiplication or division, and then push the result back to the stack.
- After processing the entire string, sum the elements in the stack to get the final result. This approach ensures that multiplication and division are handled before addition and subtraction.

#255 Verify Preorder Sequence in Binary Search Tree [Medium]

Key Insights

- A BST has the property that every node's left subtree contains values less than the node, and every right subtree contains values greater.
- Preorder traversal processes nodes as: root, left subtree, then right subtree.
- Using a monotonic stack, we can simulate constructing the BST while tracking a lower bound for allowable node values.
- When moving to a right child, update the lower bound to ensure subsequent nodes are valid.

Space & Time

Time Complexity: $O(n)$ · Each element is processed once.
Space Complexity: $O(n)$ · In the worst-case an explicit stack is used; can be optimized to $O(1)$ by reusing the input array.

Solution

We use a monotonic stack to simulate the BST construction from the preorder sequence. The process is:

- Initialize a variable lower_bound to $-\infty$.
- Iterate through each value in the preorder array: if a value is less than lower_bound, it violates BST properties and the sequence is invalid.
- While the stack is not empty and the current value is greater than the element at the top of the stack, pop from the stack and update lower_bound to the popped value. This simulates moving to the right subtree.
- Push the current value onto the stack.
- If the sequence is processed without violations, return true.

This approach efficiently ensures that each value adheres to BST requirements during preorder traversal.

#394 Decode String [Medium]

Key Insights

- Use a stack or recursion to manage nested encoded patterns.
- Process the string character by character, accumulating digits for the repeat count.
- When encountering a 'T', start a new context (recursively or via a new stack frame) for the encoded substring.
- When encountering a 'T', finish the current context and repeat the accumulated substring as needed.
- Careful handling of multi-digit numbers is essential.

Space & Time

Time Complexity: $O(n)$, where n is the length of the string.
Space Complexity: $O(n)$, for the recursion stack or the auxiliary stack used.

Solution

We can solve this problem using a recursive approach. When we see a digit, we determine the full repeat count. Upon encountering a 'T', we recursively read the encoded substring until the corresponding 'T'. Each recursive call returns the decoded substring until it hits a 'T', which is then repeated based on the previously computed count. Alternatively, an iterative solution using a stack is also feasible. As we parse the string, push the current string and number onto the stack when encountering 'T', then pop and combine when 'T' is reached. This approach correctly handles nested patterns.

Time Complexity: $O(n)$ where n is the number of asteroids, since each asteroid is pushed and popped at most once.
Space Complexity: $O(n)$ in the worst case, when no collisions occur and all asteroids remain on the stack.

Solution

The solution uses a stack to simulate the asteroid collision process. For each asteroid in the input:

- If it is moving to the right or the stack is empty, simply add it to the stack.
- If it is moving to the left, check the asteroid on top of the stack. If the top asteroid is moving to the right, they might collide. Compare sizes: If the left-moving asteroid is larger (in absolute terms), pop the stack and continue checking. If both are equal, pop the stack and do not add the current asteroid. If the right-moving asteroid is larger, the current asteroid explodes.
- If no collision occurs for the current asteroid, push it onto the stack. Finally, the stack represents the surviving asteroids' order.

#739 Daily Temperatures [Medium]

Key Insights

- Use a monotonic stack to keep track of indices of days with unresolved warmer temperatures.
- As you iterate through the temperatures, resolve previous days that have found a warmer temperature.
- The index differences yield the number of days waited until a warmer temperature.

Space & Time

Time Complexity: $O(n)$, where n is the number of temperatures, because each index is pushed and popped from the stack at most once.
Space Complexity: $O(n)$ for storing the stack and the answer array.

Solution

The solution uses a monotonic stack to track the indices whose next warmer temperature has not been found yet. As you iterate through the temperature list, compare the current temperature with the temperature at the index stored at the top of the stack. If the current temperature is higher, it means you've found a warmer day for the day represented by the index from the stack. Pop that index, calculate the difference between the current index and the popped index, and store the result. Push the current index onto the stack for future comparisons. This approach efficiently finds the answer without nested iterations.

#962 Maximum Width Ramp [Medium]

Key Insights

- We need to identify pairs (i, j) where $i < j$ and $\text{nums}[i] \leq \text{nums}[j]$.
- A monotonic decreasing stack can be constructed to maintain candidate starting indices.
- By traversing from left to right, we push indices onto the stack only when they have a smaller value than the last.
- Then, a backward pass from the end of the array allows us to efficiently match each element with the smallest possible candidate index from the stack.

Space & Time

Time Complexity: $O(n)$
Space Complexity: $O(n)$

Solution

The solution is built in two phases:

- Build a decreasing stack of indices by iterating through the array (only push an index if its value is less than the value at the current top of the stack).
- Iterate through the array backwards. For each index j , check and pop elements from the stack while $\text{nums}[j] \geq \text{nums}[i]$ (greater than or equal to the nums value at the popped index). For each valid ramp found, compute the width ($j - \text{popped index}$) and update the maximum width accordingly. This approach guarantees we examine each element a constant number of times ensuring an efficient solution.

#1214 Two Sum BSTs [Medium]

Key Insights

- Traverse the first tree to collect all node values.
- Traverse the second tree to check for each node if the complement (target - current node value) exists in the first tree's values.
- Using a hash set for the first tree values allows efficient $O(1)$ lookups.
- The BST property is not essential for the hash set solution, but can be exploited if using iterator techniques for a two-pointer approach.

Space & Time

Time Complexity: $O(n + m)$ where n and m are the number of nodes in the first and second trees respectively.
Space Complexity: $O(n)$ for storing the node values from the first tree (in worst-case scenario).

Solution

We perform a DFS (or any tree traversal) on the first BST to collect all its values in a hash set. Then, we traverse the second BST and for each node, we calculate the complement (target - node value) and check whether this complement exists in the hash set. If we find such a pair, we return true. If no such pair exists after traversing the second tree completely, we return false.
This approach is straightforward and leverages extra space (the set) for constant time lookups, yielding an overall linear time complexity relative to the number of nodes.

#1762 Buildings With an Ocean View [Medium]

Key Insights

- Processing the buildings from right to left simplifies the problem because the rightmost building always has an ocean view.
- Keep track of the highest building encountered while iterating from right to left.
- A building has an ocean view if its height is greater than the maximum height seen so far.
- Append indices meeting the criteria, then reverse the order of indices for the solution since they were collected in reverse order.

Space & Time

Time Complexity: $O(n)$ where n is the number of buildings.
Space Complexity: $O(n)$ for storing the result in the worst-case scenario.

Solution

Iterate over the "heights" array from right to left while maintaining a variable to store the maximum height encountered so far. For each building, if its height is greater than this maximum height, add its index to the results list and update the maximum height. Since indices are collected in reverse order, reverse the list before returning it. This approach ensures that each building is visited only once.

#332 Longest Valid Parentheses [Hard]

Key Insights

- Use a stack to keep track of indices where potential valid substrings begin.
- Start by pushing a dummy index (-1) to handle edge cases.
- For every 'Y', push its index onto the stack.
- For every '(', pop from the stack. If the stack becomes empty, push the current index as a new base. Otherwise, compute the length of the valid substring using the current index minus the top index of the stack.
- An alternative is the dynamic programming approach where $dp[i]$ represents the length of the longest valid substring ending at index i .

Space & Time

Time Complexity: $O(n)$ where n is the length of the string.
Space Complexity: $O(n)$ for the stack data structure.

Solution

Stack · LeetCode Mastery — By Pattern

— 2983 —

LeetCode Mastery

The stack-based solution works by maintaining indices for unmatched parentheses. Initially, a dummy index (-1) is pushed onto the stack to serve as the base for calculating subsequent valid substring lengths. As we iterate through the string:

- If the character is 'Y', we push its index onto the stack.
- If the character is '(', we pop from the stack. If the stack is empty afterwards, that means there is no valid starting position, so we push the current index to reset the base. Otherwise, we calculate the length of the current valid substring by subtracting the current index with the new top index of the stack and update the maximum length accordingly.

#42 Trapping Rain Water [Hard]

Key Insights

- The water trapped at any index is determined by the minimum of the maximum height on its left and right minus the height at that index.
- A two-pointers approach can efficiently solve the problem in one pass by maintaining left and right boundaries.
- Alternative approaches include dynamic programming with pre-computed left max and right max arrays, or using a monotonic stack to determine boundaries.

Space & Time

Time Complexity: $O(n)$
Space Complexity: $O(1)$ when using the two-pointer approach

Solution

We use a two-pointers strategy by initializing pointers at the beginning and the end of the array. Keep track of the maximum height seen so far from the left (left_max) and the right (right_max). At each step, move the pointer with the lesser height because the water trapped is determined by the shorter boundary. Compute the water at that position as the difference between the boundary (left_max or right_max) and the current height, accumulating it into the total. This approach ensures linear time scanning with constant extra space.

#84 Largest Rectangle in Histogram [Hard]

Key Insights

- Each bar can potentially extend left and right as long as the neighboring bars are not shorter.
- A monotonic (increasing) stack can be used to efficiently track indices of bars.
- When encountering a bar lower than the one on the top of the stack, pop the stack and calculate the area of the rectangle formed with the popped bar height.
- A dummy bar (of height 0) is appended at the end to ensure all bars are processed.

Space & Time

Time Complexity: $O(n)$
Space Complexity: $O(n)$

Solution

The solution employs a monotonic stack to traverse the histogram once. For each bar, while the current bar's height is less than the height at the top index of the stack, it pops from the stack and calculates the area with the popped height as the smallest bar. The width for the rectangle is determined by the difference between the current index and the index from the stack (or the current index if the stack is empty). This effectively finds the maximum rectangular area possible. A sentinel value (0) is added at the end of the histogram to flush any remaining bars from the stack.

#224 Basic Calculator [Hard]

Key Insights

- Use a stack to save previous results and signs when encountering parentheses.
- Process the string left-to-right by accumulating multi-digit numbers and applying the current sign.
- When encountering a 'Y', push the current result and sign onto the stack and reset them.

Stack · LeetCode Mastery — By Pattern

— 2984 —

LeetCode Mastery

- When encountering a 'Y', complete the current sub-expression then pop the previous state to incorporate the computed value.
- Handle whitespaces by simply skipping them.

Space & Time

Time Complexity: $O(n)$ where n is the length of the input string, since we process each character once.
Space Complexity: $O(n)$ in the worst-case scenario due to the use of a stack for nested parentheses.

Solution

The solution uses an iterative approach with a stack:
- Initialize variables: result to keep the running total, sign to handle addition/subtraction, and index to iterate over the string.
- As you iterate, build multi-digit numbers by checking for consecutive numerical characters.
- Adjust the total by adding the product of the current number and its sign.
- When encountering a 'Y', push the current result and sign onto the stack, then reset results and sign for the new sub-expression.
- When encountering a 'Y', complete the sub-expression by popping the previous result and sign, then combine.
- Skip over spaces.
- The final result is the computed value after the end of the string.
This approach effectively simulates recursion and correctly handles nested expressions and negation.

#239 Sliding Window Maximum [Hard]

Key Insights

- Use a deque (double-ended queue) to maintain the indices of potential maximum elements in a decreasing order.
- Ensure that the deque always has the current window's indices by removing elements that fall outside the current window.
- Only add elements that are greater than the ones at the back of the deque, thus preserving a monotonic decreasing order.
- The maximum for the current window is at the front of the deque.

Space & Time

Time Complexity: $O(n)$ where n is the number of elements in nums, since each element is processed at most twice.
Space Complexity: $O(k)$, as the deque stores indices for at most k elements at any time.

Solution

The solution uses a monotonic deque to maintain indices of potential maximum elements in the current window. As the window slides, we:
- Remove indices from the front if they are out of the window.
- Remove indices from the back if the current element is larger, because they cannot be the maximum if the current element is in the window.
- Append the current index.
- After the first k elements, the element at the front of the deque is the maximum for that window. This approach ensures that each element is pushed and popped from the deque only once, achieving an overall $O(n)$ time complexity.

#716 Max Stack [Hard]

Key Insights

- Use a doubly-linked list to support fast insertion and removal from the stack.
- Maintain a balanced tree (or ordered dictionary/multiset) to quickly locate the maximum element in $O(\log n)$ time.
- Map each value to its corresponding node(s) in the doubly-linked list, so that when popMax is called, you can immediately remove the corresponding node from the list.
- The double-linking allows removal of arbitrary nodes in $O(1)$, once you have the reference.

Space & Time

Time Complexity:
- push: $O(\log n)$ due to insertion in the ordered structure.
- pop: $O(1)$ for removal from the doubly-linked list, plus $O(\log n)$ for updating the tree.
- top: $O(1)$

Stack · LeetCode Mastery — By Pattern

— 2985 —

LeetCode Mastery

- peekMax: $O(1)$ or $O(\log n)$ depending on the tree implementation.
- popMax: $O(\log n)$ for looking up and removal from the tree, $O(1)$ for doubly-linked list deletion.

Space Complexity

- $O(n)$ for storing all nodes in the doubly-linked list and the tree structure mapping values to nodes.

Solution

We use two data structures:
- A doubly-linked list to store the elements in stack order. This supports fast push and pop operations and allows $O(1)$ removal when given a reference.
- An ordered structure (like a balanced BST, TreeMap in Java, or SortedList in Python) that maps each value to a list of nodes that hold that value in the linked list. This allows us to quickly determine the maximum element. When there are duplicates, we remove the one closest to the top by storing nodes in order. The trick is to keep these two structures synchronized. When an element is pushed, add its node to both the doubly-linked list and the ordered structure. When an element is removed (either via pop or popMax), remove its node from both structures.

#772 Basic Calculator III [Hard]

Key Insights

- Use recursion to handle nested expressions defined by parentheses.
- A stack can be used to correctly evaluate the expression and respect operator precedence.
- Multiplication and division have higher precedence than addition and subtraction.
- When encountering an open parenthesis, recursively compute its value until a closing parenthesis is found.
- Use immediate calculation for multiplication and division by updating the top of the stack before moving to the next operator.

Space & Time

Time Complexity: $O(n)$ where n is the length of the string, as every character is processed.
Space Complexity: $O(n)$ due to the recursion stack or auxiliary stack used for intermediate results.

Solution

We use a recursive approach combined with a stack to solve the problem. As we iterate through the string:
- Convert digits into numbers.
- When encountering an operator or parenthesis, process the previously accumulated number based on the preceding operator.
- For multiplication or division, pop the last number from the stack, apply the operation, and push the result back.
- When a '(' is encountered, recursively evaluate the substring until the corresponding ')' is reached.
- After processing all tokens, sum the values in the stack to get the final result. This method correctly handles both operator precedence and nested expressions.

#895 Maximum Frequency Stack [Hard]

Key Insights

- Use a hash map to count the frequency of each element.
- Maintain another hash map that maps frequencies to stacks (lists) of elements.
- Track the current maximum frequency to enable $O(1)$ retrieval of the most frequent element.
- When pushing an element, update its frequency and add it to the corresponding frequency stack.
- When popping an element, remove it from the stack corresponding to the maximum frequency and update the frequency count; if that stack becomes empty, decrease the current maximum frequency.

Space & Time

Time Complexity: $O(1)$ per push and pop.
Space Complexity: $O(n)$, where n is the number of elements pushed onto the stack.

Solution

The solution involves using two main data structures:

EASY

Same Tree

LeetCode · SimplifyLeet · WalkCC · LeetCode · Editorial

Tree · DFS · BFS

Lists: Grid 169

Problem:

Given the roots of two binary trees p and q , write a function to check if they are the same or not. Two binary trees are considered the same if they are structurally identical, and the nodes have the same value.

Example 1:

Input: $p = [1, 2, 3]$, $q = [1, 2, 3]$

Output: true

Example 2:

Input: $p = [1, 2]$, $q = [1, m, 1, 2]$

Output: false

Example 3:

#110 EASY
Balanced Binary Tree
[LeetCode](#) • [SimplyLeet](#) • [WalkCC](#) • [LeetCode](#) • [Editorial](#)
[Tree](#) • [DFS](#)
Lists: Grind 169

Problem:
Given a binary tree, determine if it is height-balanced.

Example 1:

Example 3:

Input: root = []

Output: true

Constraints:

- The number of nodes in the tree is in the range [0, 5000]
- $-104 \leq \text{Node.val} \leq 104$

```
Python
class Solution:
    def isBalanced(self, root: TreeLinkNode) -> bool:
        if not root:
            return True

        def maxDepth(root: TreeLinkNode) -> int:
            if not root:
                return 0
            return 1 + max(maxDepth(root.left), maxDepth(root.right))

        return (abs(maxDepth(root.left) - maxDepth(root.right)) <= 1 and
                self.isBalanced(root.left) and
                self.isBalanced(root.right))
```

```

Python
class Solution:
    def isBalanced(self, root: TreeNode) -> bool:
        def maxdepth(root: TreeNode) -> int:
            # return the height of root if root is balanced, otherwise, return -1
            if not root:
                return 0
            left = maxdepth(root.left)
            if left == -1:
                return -1

EASY

Path Sum

LeetCode - SimplyEasy - WalkCCC - LeetCode - Editorial

Tree - DFS - BFS

Little Denny Zhang

Problem:

Given the root of a binary tree and an integer targetSum, return true if the tree has a root-to-leaf path such that adding up all the values along the path equals targetSum.

A leaf is a node with no children.

Example 1:

Trees & BST - LeetCode - By Pattern

— 3039 —

LeetCode

Input: root = [5,4,8,11,null,13,4,7,2,null,null,null,1], targetSum = 22

Output: true

Explanation: The root-to-leaf path with the target sum is shown.

Example 2:

Input: root = [1,2,3], targetSum = 5

Output: false

Explanation: There are two root-to-leaf paths in the tree:

(1 -> 2): The sum is 3.

(1 -> 3): The sum is 4.

There is no root-to-leaf path with sum = 5.

Example 3:

Trees & BST - LeetCode - By Pattern

— 3040 —

LeetCode

Input: root = [], targetSum = 0
Output: false
Explanation: Since the tree is empty, there are no root-to-leaf paths.

Constraints:

- The number of nodes in the tree is in the range [0, 5000].
- -1000 <= Node.val <= 1000
- -1000 <= targetSum <= 1000

>> Brute Force [Trees & BST] Interview Prep

Python

```

# Brute Force Approach
class Solution:
    def hasPathSum(self, root, targetSum):
        # Brute Force - collect inorder, then process sorted list
        vals = []
        def collect(node):
            if not node: return
            collect(node.left)
            vals.append(node.val)
            collect(node.right)
        collect(root)
        return vals[0] if vals else 0

```

Python

```

# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right

def hasPathSum(root, targetSum):
    # If the current node is None, no valid path exists
    if not root:
        return False
    # Check if the current node is a leaf node
    if not root.left and not root.right:
        # If the current node's value equals the target sum
        return targetSum == root.val
    # Recursively check the left and right subtrees with the updated target sum
    return hasPathSum(root.left, targetSum - root.val) or hasPathSum(root.right, targetSum - root.val)

# Example usage:
# root = TreeNode(1, TreeNode(4, TreeNode(11, TreeNode(7)), TreeNode(8, TreeNode(13),
#   TreeNode(4, None, TreeNode(1))))
# print(hasPathSum(root, 22)) # Output: True

Invert Binary Tree

LeetCode - SimplifyLeet - WalkCC - LeetCode - Editorial

Tree - DFS - BFS

Like: 100

Views: 100

Problem:

Given the root of a binary tree, invert the tree, and return its root.

Example 1:

Example 2:

Input: root = [2,1,3]
Output: [2,3,1]

Example 3:
Input: root = []
Output: []

Constraints:

- The number of nodes in the tree is in the range [0, 100].
- -100 <= Node.val <= 100

```
Python
# Definition for a binary tree node.
class TreeNode:
    def __init__(self, val=0, left=None, right=None):
        self.val = val
        self.left = None
        self.right = None

class Solution:
    def invertTree(self, root: Optional[TreeNode]) -> Optional[TreeNode]:
        # Base case: If the node is None, return None.
        if not root:
            return None
        # Recursively invert the left and right subtrees.
        left_inverted = self.invertTree(root.left)
        right_inverted = self.invertTree(root.right)
        # Swap the left and right subtrees.
        root.left, root.right = right_inverted, left_inverted
        return root

Python
class Solution:
    def invertTree(self, root: Optional[TreeNode]) -> Optional[TreeNode]:
        if not root:

EASY

Closest Binary Search Tree Value

LeetCode - SimplifyLeetCode - WUCC - LeetCode - Editorial

Binary Search - Tree - DFS - BST

LeetCode Premium 30

Problem:

Given the root of a binary search tree and a target value, return the value in the BST that is closest to the target. If there are multiple answers, print the smallest.

Example 1:

Trees & BST - LeetCode - By Pattern

— 3056 —

LeetCode

Input: root = [4,2,5,1,3], target = 3.714286
Output: 4

Example 2:

Input: root = [1], target = 4.428571
Output: 1

Constraints:

- The number of nodes in the tree is in the range [1, 104].
- 0 <= Node.val <= 100
- 109 <= target <= 109

Python

Python

```

// Definition for a binary tree node.
// #include<bits/stdc++.h>
// using namespace std;
// int main() {
//     int n;
//     cin >> n;
//     int arr[n];
//     for (int i = 0; i < n; i++) {
//         cin >> arr[i];
//     }
//     // Insert the nodes
//     int root = arr[0];
//     int left = -1, right = -1;
//     for (int i = 1; i < n; i++) {
//         if (arr[i] < root) {

#501 EASY
Find Mode in Binary Search Tree
LeetCode - Simplest - MathCC - LeetCode - Editorial

Tree - DFS - BST
List: Denny Zhang

Problem:

Given the root of a binary search tree (BST) with duplicates, return all the mode(s) (i.e., the most frequently occurred element) in it.

If the tree has more than one mode, return them in any order.

Assume a BST is defined as follows:

- The left subtree of a node contains only nodes with keys less than or equal to the node's key.
- The right subtree of a node contains only nodes with keys greater than or equal to the node's key.
- Both the left and right subtrees must also be binary search trees.

Example 1:

Trees & BST - LeetCode - By Pattern

— 3066 —

LeetCode

Input: root = [1,null,2,2]
Output: [2]
Example 2:
Input: root = [0]
Output: [0]
Constraints:
• The number of nodes in the tree is in the range [1, 104].
• -105 <= Node.val <= 105
Follow up: Could you do that without using any extra space? (Assume that the implicit stack space incurred due to recursion does not count).

Problem:
 Given the root of a binary tree, return the length of the diameter of the tree.
 The diameter of a binary tree is the length of the longest path between any two nodes in a tree. This path may or may not pass through the root.
 The length of a path between two nodes is represented by the number of edges between them.
 Example 1:

Input: root = [1,2,3,4,5]
 Output: 3
 Explanation: 3 is the length of the path [4,2,1,3] or [5,2,1,3].
 Example 2:
 Input: root = [1,2]
 Output: 1
 Constraints:
 • The number of nodes in the tree is in the range [1, 104].
 • -100 <= Node.val <= 100

Python

```

# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):

Subtree of Another Tree

LeetCode - Simplify - WalkCC - LeetCode - Editorial

Tree - DFS - String Matching

Like (100)

Problem:

Given the roots of two binary trees root and subRoot, return true if there is a subtree of root with the same structure and node values of subRoot and false otherwise.

A subtree of a binary tree tree is a tree that consists of a node in tree and all of this node's descendants. The tree tree could also be considered as a subtree of itself.

Example 1:

Trees & BST - LeetCode - By Pattern

— 3090 —

LeetCode

Input: root = [3,4,5,1,2], subRoot = [4,1,2]
 Output: true
 Example 2:

Input: root = [3,4,5,1,2,null,null,null,0], subRoot = [4,1,2]
 Output: false

- Constraints:
- The number of nodes in the root tree is in the range [1, 2000].
 - The number of nodes in the subRoot tree is in the range [1, 1000].
 - $-104 \leq \text{root.val} \leq 104$
 - $-104 \leq \text{subRoot.val} \leq 104$

Validate Binary Search Tree

LeetCode - SimplyLeetCode - WubCC - LeetCode - Editorial

Tree - DFS - BST

Like 100 100

Problem:

Given the root of a binary tree, determine if it is a valid binary search tree (BST).

A valid BST is defined as follows:

- The left subtree of a node contains only nodes with keys strictly less than the node's key.
- The right subtree of a node contains only nodes with keys strictly greater than the node's key.
- Both the left and right subtrees must also be binary search trees.

Example 1:

```

graph TD
    2((2)) --> 1((1))
    2 --> 3((3))

```

Input: root = [2,1,3]
Output: true

Example 2:

```

graph TD
    5((5)) --> 1((1))
    5 --> 4((4))
    4 --> 3((3))
    4 --> 6((6))

```

Input: root = [5,1,4,null,null,3,6]
Output: false

Explanation: The root node's value is 5 but its right child's value is 4.

Constraints:

- The number of nodes in the tree is in the range [1, 104].
- 231 <= Node.val <= 231 - 1

Python

```

# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
class Solution:
    def isValidBST(self, root: TreeNode) -> bool:
        # Helper function to recursively validate nodes
        def validate(node, low, high):
            if not node:
                return True
            if not (low < node.val < high):
                return False
            return (
                validate(node.left, low, node.val)
                and validate(node.right, node.val, high)
            )
        return validate(root, float("-inf"), float("inf"))

Binary Tree Level Order Traversal

[LeetCode](#) · [SimpleLine](#) · [WuJieCC](#) · [LeetCode](#) · [Editorial](#)

Tree · BFS

List: Grid 169

Problem:

Given the root of a binary tree, return the level order traversal of its nodes' values. (i.e., from left to right, level by level).

Example 1:

Input: root = [3,9,20,null,null,15,7]
Output: [[3],[9,20],[15,7]]

Example 2:

Trees & BST · LevelMastery · By Pattern

— 3115 —

LevelMastery

Input: root = [1]
Output: [[1]]

Example 3:

Input: root = []
Output: []

Constraints:

- The number of nodes in the tree is in the range [0, 2000].
- -1000 <= Node.val <= 1000

Python

Python

```
# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
from collections import deque

class Solution:
    def levelOrder(self, root: TreeNode) -> List[List[int]]:
        # Return an empty list if the tree is empty.
        if not root:
            return []

        result = [] # Final result list containing values of each level.
        queue = deque([root]) # Initiation the queue with the root node.

        # Process nodes level by level.
        while queue:
            level_size = len(queue) # Number of nodes at the current level.
            level_nodes = [] # List to hold node values at the current level.

            for _ in range(level_size):
                node = queue.popleft() # Dequeue the next node.

                level_nodes.append(node.val)
                # Enqueue left child if it exists.
                if node.left:
                    queue.append(node.left)
                # Enqueue right child if it exists.
                if node.right:
                    queue.append(node.right)
            # Append the current level's values to the result.
            result.append(level_nodes)

        return result

Binary Tree Zigzag Level Order Traversal

LeetCode - [SimplifyLeetCode](#) - [WuJieCC](#) - [LeetCode](#) - [Editorial](#)

Tree - BFS

Little Grind 169

Problem:

Given the root of a binary tree, return the zigzag level order traversal of its nodes' values. (i.e., from left to right, then right to left for the next level and alternate between).

Example 1:

Input: root = [3,9,20,null,null,15,7]
Output: [[3],[20,9],[15,7]]

Example 2:

Input: root = [1]
Output: [[1]]

Example 3:

Input: root = []
Output: []

Constraints:

- The number of nodes in the tree is in the range [0, 2000].
- -100 <= Node.val <= 100

MEDIUM

Construct Binary Tree from Preorder and Inorder Traversal

LeetCode - Simple - Medium - Easy - LeetCode - Editorial

Array - Hash Table - Tree - DFS

Like Grind 109

Problem:

Given two integer arrays preorder and inorder where preorder is the preorder traversal of a binary tree and inorder is the inorder traversal of the same tree, construct and return the binary tree.

Example 1:

Input: preorder = [3,9,20,15,7], inorder = [9,3,15,20,7]
Output: [3,9,20,null,null,15,7]

Example 2:

Input: preorder = [-1], inorder = [-1]
Output: [-1]

Constraints:

- 1 <= preorder.length <= 3000
- inorder.length == preorder.length
- 3000 <= preorder[i], inorder[i] <= 3000
- preorder and inorder consist of unique values.
- Each value of inorder also appears in preorder.
- preorder is guaranteed to be the preorder traversal of the tree.
- inorder is guaranteed to be the inorder traversal of the tree.

Python
Python

```

# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right
#
class Solution:
    def buildTree(self, preorder: List[int], inorder: List[int]) -> TreeNode:
        # Create a hash map to store the index of each element in the inorder array
        inorder_index = {val: i for i, val in enumerate(inorder)}
        # Recursive helper function to build the tree
        def helper(pre_start, in_left, in_right):
            # Base case: if there are no elements to construct subtree
            if in_left > in_right:
                return None
            # Pick the pre_start element as a root
            root_val = preorder[pre_start]
            root = TreeNode(root_val)
            # Get the inorder index of the root
            in_index = inorder_index[root_val]

#230 MEDIUM
Kth Smallest Element in a BST

Trees & BST - LeetCode - By Pattern — 3183 — LeetCode

LeetCode - SimplyList - WalkCC - LeetCode - Editorial
Tree - DFS - BST
LeetCode 230

Problem:
Given the root of a binary search tree, and an integer k, return the kth smallest value (1-indexed) of all the values of the nodes in the tree.
Example 1:

Input: root = [3,1,4,null,2], k = 1
Output: 1
Example 2:

Input: root = [5,3,6,2,4,null,null,1], k = 3
Output: 3
Constraints:
• The number of nodes in the tree is n.
• 1 ≤ k ≤ n ≤ 104
• 0 ≤ Node.val ≤ 104
Follow up: If the BST is modified often (i.e., we can do insert and delete operations) and you need to find the kth smallest frequently, how would you optimize?

#235 MEDIUM
Lowest Common Ancestor of a Binary Search Tree

LeetCode - Binary Search Tree - Medium - Editorial

Tree - DFS - BST

LeetCode Grind 109

Problem:
Given a binary search tree (BST), find the lowest common ancestor (LCA) node of two given nodes in the BST.

According to the definition of LCA on Wikipedia: "The lowest common ancestor is defined between two nodes p and q as the lowest node in T that has both p and q as descendants (where we allow a node to be a descendant of itself)."

Example 1:

Input: root = [6,2,8,0,4,7,9,null,null,3,5], p = 2, q = 8
Output: 6
Explanation: The LCA of nodes 2 and 8 is 6.

Example 2:

Input: root = [6,2,8,0,4,7,9,null,null,3,5], p = 2, q = 4
Output: 2
Explanation: The LCA of nodes 2 and 4 is 2, since a node can be a descendant of itself according to the LCA definition.

Example 3:

Input: root = [2,1], p = 2, q = 1
Output: 2

Constraints:

- The number of nodes in the tree is in the range [2, 105].
- 109 <= Node.val <= 109
- All Node.val are unique.
- p != q
- p and q will exist in the BST.

Given a binary tree, find the lowest common ancestor (LCA) of two given nodes in the tree.
According to the definition of LCA on Wikipedia: "The lowest common ancestor is defined between two nodes p and q as the lowest node in T that has both p and q as descendants (where we allow a node to be a descendant of itself)."

Example 1:

Input: root = [3,5,1,6,2,0,8,null,null,7,4], p = 5, q = 1
Output: 3
Explanation: The LCA of nodes 5 and 1 is 3.

Example 2:

Input: root = [3,5,1,6,2,0,8,null,null,7,4], p = 5, q = 4
Output: 5
Explanation: The LCA of nodes 5 and 4 is 5, since a node can be a descendant of itself according to the LCA definition.

Example 3:

Input: root = [1,2], p = 1, q = 2
Output: 1

Count Unival Subtrees

LeetCode - [Simplify](#) - [WuCC](#) - [LeetCode](#) - [Editorial](#)

Tree - DFS

Little Premium 98

Problem:
Given the root of a binary tree, return the number of uni-value subtrees.

A uni-value subtree means all nodes of the subtree have the same value.

Example 1:

```

graph TD
    5((5)) --- 1((1))
    5 --- 5r((5))
    1 --- 5l((5))
    1 --- 5b((5))
    5r --- 5c((5))

```

Input: root = [5,1,5,5,5,null,5]
Output: 4

Example 2:

```

Input: root = []
Output: 0

```

Example 3:

```

Input: root = [5,5,5,5,5,null,5]
Output: 6

```

Constraints:

- The number of the node in the tree will be in the range [0, 1000].
- 1000 <= Node.val <= 1000

Python

```

# Definition for a binary tree node.
# class TreeNode:
#     def __init__(self, val=0, left=None, right=None):
#         self.val = val
#         self.left = left
#         self.right = right

class Solution:
    def countUnivalSubtrees(self, root: TreeNode) -> int:
        # Initialization
        self.count = 0

        # Helper function performs postorder DFS
        def isUnival(node):
            # Base case: null nodes are considered unival
            if node is None:
                return True

            # Recursion calls for left and right subtrees
            leftUnival = isUnival(node.left)
            rightUnival = isUnival(node.right)

            # Check if left child exists and its value does not match current node's value
            if node.left and node.left.val != node.val:
                leftUnival = False

            # Check if right child exists and its value does not match current node's value
            if node.right and node.right.val != node.val:
                rightUnival = False

            # If either left or right subtree is not unival, then the current subtree is not unival
            if not leftUnival or not rightUnival:
                return False

            # Increment the count if the subtree rooted at the current node is unival
            self.count += 1
            return True
        else:
            return False

        # Base recursion from root
        isUnival(root)
        return self.count

# Example usage:
# Construct the binary tree: [5,1,5,5,5,null,5]
# root = TreeNode(5)
# root.left = TreeNode(1)
# root.right = TreeNode(5)
# root.left.left = TreeNode(5)
# root.left.right = TreeNode(5)
# root.right.left = TreeNode(5)
# print(Solution().countUnivalSubtrees(root)) # Output: 4

#285 MEDIUM
Inorder Successor in BST
LeetCode - [SimpleLink](#) - [WikiCC](#) - [LeetCode](#) - [Editorial](#)

Tree - DFS - BST
Lists - Grind 169

Problem:
Given the root of a binary search tree and a node p in it, return the in-order successor of that node in the BST. If the given node has no in-order successor in the tree, return null.
The successor of a node p is the node with the smallest key greater than p.val.

Example 1:

Input: root = [2,1,3], p = 1
Output: 2
Explanation: 1's in-order successor node is 2. Note that both p and the return value is of TreeNode type.

Example 2:

Input: root = [5,3,6,2,4,null,null,1], p = 6
Output: null
Explanation: There is no in-order successor of the current node, so the answer is null.

Constraints:

- The number of nodes in the tree is in the range [1, 104].
- 105 <= Node.val <= 105
- All nodes will have unique values.

Python
Python

```

Binary Tree Longest Consecutive Sequence

LeetCode · SimplifyLeetCode · WUCC · LeetCode · Editorial

Tree · DFS

Like · Premium 98

Problem:

Given the root of a binary tree, return the length of the longest consecutive sequence path.

A consecutive sequence path is a path where the values increase by one along the path.

Note that the path can start at any node in the tree, and you cannot go from a node to its parent in the path.

Example 1:

Trees & BST · LeetCodeMastery — By Pattern

— 3229 —

LeetCodeMastery

Input: root = [2,null,3,2,4,null,null,null,5]

Output: 3

Explanation: Longest consecutive sequence path is 3-4-5, so return 3.

Example 2:

Trees & BST · LeetCodeMastery — By Pattern

— 3230 —

LeetCodeMastery

Input: root = [2,null,3,2,null,1]

Output: 2

Explanation: Longest consecutive sequence path is 2-3, not 3-2-1, so return 2.

Constraints:

- The number of nodes in the tree is in the range [1, 3 * 10⁴].
- -3 * 10⁴ <= Node.val <= 3 * 10⁴

Python

Python

```
# Definition for a binary tree node.
class TreeNode:
    def __init__(self, val=0, left=None, right=None):
        self.val = val
        self.left = left
        self.right = right

class Solution:
    def longestConsecutive(self, root: TreeNode) -> int:

#314 MEDIUM
Binary Tree Vertical Order Traversal
LeetCode - Solution - Hash Table - DFS - Sorting
Hash Table - Tree - DFS - Sorting
List: Premium 98

Problem:
Given the root of a binary tree, return the vertical order traversal of its nodes' values. (i.e., from top to bottom, column by column).
If two nodes are in the same row and column, the order should be from left to right.
Example 1:

Input: root = [3,9,20,null,null,15,7]
Output: [[9],[3,15],[20],[7]]

Example 2:

Input: root = [3,9,8,4,0,1,7]
Output: [[4],[9],[3,0,1],[8],[7]]

Example 3:

Input: root = [1,2,3,4,10,9,11,null,5,null,null,null,null,null,6]
Output: [[4],[2,5],[1,10,9,6],[3],[11]]

- Constraints:
- The number of nodes in the tree is in the range [0, 100].
 - -100 <= Node.val <= 100

[*] Trees & BST — Pattern Solution (matched from community answers)

LeetMastery

Problem:
Given the root of a binary tree, find the largest subtree, which is also a Binary Search Tree (BST), where the largest means subtree has the largest number of nodes.

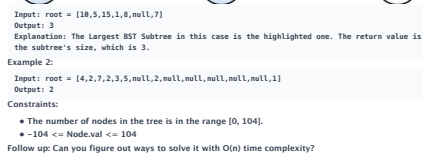

A Binary Search Tree (BST) is a tree in which all the nodes follow the below-mentioned properties:

- The left subtree values are less than the value of their parent (root) node's value.
- The right subtree values are greater than the value of their parent (root) node's value.

Note: A subtree must include all of its descendants.

Example 1:

LeetMastery

Python

LeetMastery

Python

LeetMastery

```

from dataclasses import dataclass

@dataclass(frozen=True)
class T:
    mx: int # the minimum value in the subtree
    mx: int # the maximum value in the subtree
    size: int # the size of the subtree

    }
    dfs(root)
    return ans
}

```

Input: root = [1,2,3,4,5]
Output: [4,5,3],[2],[1]
Explanation: [3,5,4],[2],[1]] and [3,4,5],[2],[1]] are also considered correct answers since per each level it does not matter the order on which elements are returned.

Example 2:

Input: root = [1]
Output: [1]

Constraints:

- The number of nodes in the tree is in the range [1, 100].
- 100 <= Node.val <= 100

Find Leaves of Binary Tree

LeetCode - Interview - LeetCode - LeetCode - Editorial

Tree - DFS - Sorting

Like Premium 98

Problem:

Given the root of a binary tree, collect a tree's nodes as if you were doing this:

- Collect all the leaf nodes.
- Remove all the leaf nodes.
- Repeat until the tree is empty.

Example 1:

```

# Definition for a binary tree node.
# type TreeNode struct {
#     int val;
#     *Left *TreeNode;
#     *Right *TreeNode;
# }
class Solution {
    def findLeaves(self, root: TreeNode):
        result = []
        def getheight(node):
            # Base case: when the node is None, return 0.
            if not node:
                return 0
            # Recursively find the height of left and right subtrees.
            left_height = getheight(node.left)
            right_height = getheight(node.right)
            # Current node's height is one of left/right heights plus one.
            current_height = max(left_height, right_height) + 1
            # Remove the result list has a sublist for the current height.
            if len(result) < current_height:
                result.append([])
            # Append the current node value to the corresponding height bucket.
            result[current_height - 1].append(node.val)
            return current_height
        getheight(root)
        return result

```

Python

```

#545 MEDIUM
Boundary of Binary Tree
[LeetCode](#) - [SimplifyLeet](#) - [WalkCC](#) - [LeetCode](#) - [Editorial](#)
 Tree - DFS
 LeetCode Premium 98

Problem:
 The boundary of a binary tree is the concatenation of the root, the left boundary, the leaves ordered from left-to-right, and the reverse order of the right boundary.
 The left boundary is the set of nodes defined by the following:

- The root node's left child is in the left boundary. If the root does not have a left child, then the left boundary is empty.
- If a node is in the left boundary and has a left child, then the left child is in the left boundary.
- If a node is in the left boundary, has no left child, but has a right child, then the right child is in the left boundary.
- The leftmost leaf is not in the left boundary.

The right boundary is similar to the left boundary, except it is the right side of the root's right subtree. Again, the leaf is not part of the right boundary, and the right boundary is empty if the root does not have a right child.
 The leaves are nodes that do not have any children. For this problem, the root is not a leaf.
 Given the root of a binary tree, return the values of its boundary.

Example 2:

Input: root = [1,2,3,4,5,6,null,null,7,8,9,10]
Output: [1,2,4,7,8,9,10,6,3]
Explanation:
- The left boundary follows the path starting from the root's left child 2 → 4.
4 is a leaf, so the left boundary is [2].
- The right boundary follows the path starting from the root's right child 3 → 6 → 10.
10 is a leaf, so the right boundary is [3,6], and in reverse order is [6,3].
- The leaves from left to right are [2,7,8,9,10].
Concatenating everything results in [1] + [2] + [4,7,8,9,10] + [6,3] = [1,2,4,7,8,9,10,6,3].
Constraints:
• The number of nodes in the tree is in the range [1, 104].
• -1000 ≤ Node.val ≤ 1000

Python

```
# Definition for a binary tree node.
class TreeNode:
    def __init__(self, val=0, left=None, right=None):
        self.val = val
        self.left = left
        self.right = right

class Solution:
    def boundaryOfBinaryTree(self, root: TreeNode) -> List:
        if not root:
            return []

        # Check if a node is a leaf.
        def isLeaf(node):

                if not isLeaf(node):
                    boundary.append(node.val)
                # Preorder visit node, if not present then right child.
                if node.left:
                    node = node.left
                else:
                    node = node.right

        # Add leaf nodes using BFS.
        def addLeaves(node, leaves):
            if not node:
                return
            if isLeaf(node):
                leaves.append(node.val)
            else:
                addLeaves(node.left, leaves)
                addLeaves(node.right, leaves)

        # Add right boundary nodes in reverse order (excluding leaves).
        def addRightBoundary(node, boundary):
            temp = []
            while node:
                if not isLeaf(node):
                    temp.append(node.val)
                if node.right:
                    node = node.right
                else:
                    node = node.left
            # Append in reverse order.
            while temp:
                boundary.append(temp.pop())
```

```
boundary = []
# Add root value if it is not a leaf.
if not isLeaf(root):
    boundary.append(root.val)
addLeftBoundary(root.left, boundary)
addLeaves(root, boundary)
addRightBoundary(root.right, boundary)
return boundary

# Example usage:
# Construct a binary tree and call boundaryOfBinaryTree(root)

Python
class Solution:
    def boundaryOfBinaryTree(self, root: TreeNode | None) -> List[int]:
        if not root:
            return []
        ans = [root.val]

        def dfs(root: TreeNode | None, lb: bool, rb: bool):
            # 1. root left is left boundary if root is left boundary.

Binary Tree Longest Consecutive Sequence II

LeetCode - SimplyLeetCode - WubCC - LeetCode - Editorial

Tree - DFS
Little Premium 98

Problem:

Given the root of a binary tree, return the length of the longest consecutive path in the tree. A consecutive path is a path where the values of the consecutive nodes in the path differ by one. This path can be either increasing or decreasing.

For example, [1,2,3,4] and [4,3,2,1] are both considered valid, but the path [1,2,4,3] is not valid. On the other hand, the path can be in the child-Parent-child order, where not necessarily be parent-child order.

Example 1:

Input: root = [1,2,3]

Output: 2

Explanation: The longest consecutive path is [1, 2] or [2, 1].

Example 2:

Input: root = [2,1,3]

Output: 3

Explanation: The longest consecutive path is [1, 2, 3] or [3, 2, 1].

Constraints:

- The number of nodes in the tree is in the range [1, 3 * 10⁴].
- 3 * 10⁴ <= Node.val <= 3 * 10⁴

#662 MEDIUM
Maximum Width of Binary Tree
LeetCode - Solution - WalkCC - LeetCode - Editorial
Tree - BFS
List: Grind 169

Problem:
Given the root of a binary tree, return the maximum width of the given tree.
The maximum width of a tree is the maximum width among all levels.

Python

class Solution:
    def widthOfBinaryTree(self, root: Optional[TreeNode]) -> int:
        if not root:
            return 0
        queue = deque([(root, 0)])
        max_width = 0
        while queue:
            level_size = len(queue)
            first_index = None
            last_index = None
            for i in range(level_size):
                node, index = queue.popleft()
                if i == 0:
                    first_index = index
                if i == level_size - 1:
                    last_index = index
                if node.left:
                    queue.append((node.left, index * 2))
                if node.right:
                    queue.append((node.right, index * 2 + 1))
            max_width = max(max_width, last_index - first_index + 1)
        return max_width
```

The width of one level is defined as the length between the end-nodes (the leftmost and rightmost non-null nodes), where the null nodes between the end-nodes that would be present in a complete binary tree extending down to that level are also counted into the length calculation. It is guaranteed that the answer will in the range of a 32-bit signed integer.

Example 1:

```
Input: root = [1,3,2,5,3,null,9]
Output: 4
Explanation: The maximum width exists in the third level with length 4 (5,3,null,9).
```

Example 2:

```
Input: root = [1,3,2,5,3,null,9]
Output: 4
Explanation: The maximum width exists in the third level with length 4 (5,3,null,9).
```

```
Input: root = [1,3,2,5,null,null,9,6,null,7]
Output: 7
Explanation: The maximum width exists in the fourth level with length 7 (6,null,null,null,null,7).
```

Example 3:

Input: root = [1,3,2,5]
Output: 2
Explanation: The maximum width exists in the second level with length 2 ([3,2]).

- Constraints:
- The number of nodes in the tree is in the range [1, 3000].
 - -100 <= Node.val <= 100

All Nodes Distance K in Binary Tree

LeetCode - SimplifyLeetCode - LeetCode - Editorial

Hash Table - Tree - DFS - BFS

Uppis Grind 109

Problem:

Given the root of a binary tree, the value of a target node target, and an integer k, return an array of the values of all nodes that have a distance k from the target node.

You can return the answer in any order.

Example 1:

Input: root = [3,5,1,6,2,0,8,null,null,7,4], target = 5, k = 2

Output: [7,4,1]

Explanation: The nodes that are a distance 2 from the target node (with value 5) have values 7, 4, and 1.

Example 2:

Input: root = [1], target = 1, k = 3

Output: []

Constraints:

- The number of nodes in the tree is in the range [1, 500].
- 0 <= Node.val <= 500
- All the values Node.val are unique.
- target is the value of one of the nodes in the tree.
- 0 <= k <= 1000

Maximum Average Subtree
LeetCode - Simplify - [LeetCode](#) - [LeetCode](#) - [LeetCode](#)

Tree - DFS

LeetCode Premium 98

Problem:

Given the root of a binary tree, return the maximum average value of a subtree of that tree. Answers within 10⁻⁵ of the actual answer will be accepted.

A subtree of a tree is any node of that tree plus all its descendants.

The average value of a tree is the sum of its values, divided by the number of nodes.

Example 1:

Input: root = [5,6,1]
Output: 6.00000
Explanation:
For the node with value = 5 we have an average of (5 + 6 + 1) / 3 = 4.
For the node with value = 6 we have an average of 6 / 1 = 6.
For the node with value = 1 we have an average of 1 / 1 = 1.
So the answer is 6 which is the maximum.

Example 2:

Input: root = [0,null,1]
Output: 1.00000

Constraints:

- The number of nodes in the tree is in the range [1, 104].
- 0 <= Node.val <= 105

Clone N-ary Tree

LeetCode - SimplyList - WuhCC - LeetCode - Editorial

Hash Table - Tree - DFS - BFS

Like Premium 98

Problem:

Given a root of an N-ary tree, return a deep copy (clone) of the tree.

Each node in the n-ary tree contains a val (int) and a List(ListNode) of its children.

```
class Node {
    public int val;
    public List<Node> children;
}
```

N-ary-Tree input serialization is represented in their level order traversal, each group of children is separated by the null value (See examples).

Example 1:

Input: root = [1,null,3,2,4,null,5,6]
Output: [1,null,3,2,4,null,5,6]
Example 2:

Input: root =
[1,null,2,3,4,5,null,null,6,7,null,8,null,9,10,null,null,11,null,12,null,13,null,null,14]

Output:
[1,null,2,3,4,5,null,null,6,7,null,8,null,9,10,null,null,11,null,12,null,13,null,null,14]

Constraints:

- The depth of the n-ary tree is less than or equal to 1000.
- The total number of nodes is between [0, 104].

Follow up: Can your solution work for the graph problem?

Diameter of N-Ary Tree

LeetCode — [SimpleLink](#) — [WikiCC](#) — [LeetCode](#) — [Editorial](#)

Tree — DFS

List: Premium 98

Problem:

Given a root of an N-ary tree, you need to compute the length of the diameter of the tree.

The diameter of an N-ary tree is the length of the longest path between any two nodes in the tree. This path may or may not pass through the root.

(N-ary-Tree input serialization is represented in their level order traversal, each group of children is separated by the null value.)

Example 1:

- The depth of the n-ary tree is less than or equal to 1000.
- The total number of nodes is between [1, 1004].

Python

Python

```
# Definition for a Node.
class Node:
    def __init__(self, val=None, children=None):
        self.val = val
        self.children = children if children is not None else []

class Solution:
    def diameter(self, root: 'Node') -> int:
        # Global variable to keep track of the maximum diameter found so far.
        self.max_diameter = 0

        def dfs(node):
            if not node:
                return 0 # Base case: if the node is None, return depth 0

            # Variables to hold the top two maximum depths from the children.
            max_depth1, max_depth2 = 0, 0

            # Traverse over each child to compute their maximum depths.
            for child in node.children:
                child_depth = dfs(child) # Recurse on the child
                # Update the top two maximum depths.
                if child_depth > max_depth1:
                    max_depth2 = max_depth1
                    max_depth1 = child_depth
                elif child_depth > max_depth2:

Problem:

Given two nodes of a binary tree p and q, return their lowest common ancestor (LCA).

Each node will have a reference to its parent node. The definition for Node is below:

```

class Node {
public:
    Node left;
    Node right;
    Node parent;
};

```

According to the definition of LCA on Wikipedia: "The lowest common ancestor of two nodes p and q in a tree T is the lowest node that has both p and q as descendants (where we allow a node to be a descendant of itself)."

Example 1:

Trees & BST · LeastMastery · By Pattern

— 3367 —

LeastMastery

Input: root = [3,5,1,6,2,0,8,null,null,7,4], p = 5, q = 1
 Output: 3
 Explanation: The LCA of nodes 5 and 1 is 3.

Example 2:

Input: root = [3,5,1,6,2,0,8,null,null,7,4], p = 5, q = 4
 Output: 5
 Explanation: The LCA of nodes 5 and 4 is 5 since a node can be a descendant of itself according to the LCA definition.

Example 3:

Input: root = [1,2], p = 1, q = 2
 Output: 1

Constraints:

- The number of nodes in the tree is in the range [2, 105].
- 109 <= Node.val <= 109
- All Node.val are unique.
- p != q
- p and q exist in the tree.

Binary Tree Maximum Path Sum

LeetCode - SimplifyLeetCode - WsLCC - LeetCode - Editorial

Dynamic Programming - Tree - DFS

Lists Grid 169

Problem:

A path in a binary tree is a sequence of nodes where each pair of adjacent nodes in the sequence has an edge connecting them. A node can only appear in the sequence at most once. Note that the path does not need to pass through the root.

The path sum of a path is the sum of the node's values in the path.

Given the root of a binary tree, return the maximum path sum of any non-empty path.

Example 1:

Input: root = [1,2,3]
Output: 6
Explanation: The optimal path is 2 -> 1 -> 3 with a path sum of 2 + 1 + 3 = 6.

Example 2:

Input: root = [-10,9,20,null,null,15,7]
Output: 42
Explanation: The optimal path is 15 -> 20 -> 7 with a path sum of 15 + 20 + 7 = 42.
Constraints:
• The number of nodes in the tree is in the range [1, 3 * 10⁴].
• -1000 <= Node.val <= 1000

Python

Python

```

// Definition for a binary tree node.
// class TreeNode {
//     int val;
//     TreeNode left;
//     TreeNode right;
//     TreeNode() {}
//     TreeNode(int x) { val = x; }
// }

class Solution {
    def maxPathSum(self, root: Optional[TreeNode]) -> int:
        # Initialize global maximum path sum with a very small number
        self.global_max = float('-inf')

        def dfs(node: Optional[TreeNode]) -> int:
            if not node:
                return 0

            # Recursively calculate the max gain from left and right children, discard negative gains
            left_gain = max(dfs(node.left), 0)
            right_gain = max(dfs(node.right), 0)

            # Current maximum including both left and right gains
            current_max = node.val + left_gain + right_gain

297 HARD Serialize and Deserialize Binary Tree

LeetCode - Implementation - Python3 - LeetCode - Editorial

String - Tree - DFS - BFS - Design

Lists Grind 189

Problem:

Serialization is the process of converting a data structure or object into a sequence of bits so that it can be stored in a file or memory buffer, or transmitted across a network connection link to be reconstructed later in the same or another computer environment.

Design an algorithm to serialize and deserialize a binary tree. There is no restriction on how your serialization/deserialization algorithm should work. You just need to ensure that a binary tree can be serialized to a string and this string can be deserialized to the original tree structure.

Clarification: The input/output format is the same as how LeetCode serializes a binary tree. You do not necessarily need to follow this format, so please be creative and come up with different approaches yourself.

Example 1:

Trees & BST - LeetCode - By Pattern

— 3387 —

LeetCode

Input: root = [1,2,3,null,null,4,5]
Output: ["1,2,3,null,null,4,5"]

Example 2:

Input: root = []
Output: []

Constraints:

- The number of nodes in the tree is in the range [0, 104].
- 1000 <= Node.val <= 1000

Python

Quick Review — Trees & BST 37 questions · insights · solution

#100 Same Tree [Easy]

Key Insights

- Use recursion to compare nodes in both trees.
- If both nodes being compared are null, they are the same.
- If one node is null while the other is not, the trees differ.
- Check if current nodes' values match, then recursively verify the left and right subtrees.

Space & Time

Time Complexity: $O(n)$, where n is the number of nodes in the trees, since every node is visited once.
Space Complexity: $O(n)$ in the worst-case (unbalanced tree), due to recursion call stack usage. In a balanced tree, the space would be $O(\log n)$.

Solution

The problem can be solved using a recursive approach (Depth-First Search) where we compare the current nodes from both trees. If the current nodes are both null, they match. If one is null, then the trees are not identical. For non-null nodes, check if the values are equal. Then, recursively apply the same logic on the left and right children of the nodes. This approach ensures that both the structure and the node values are identical across the two trees.

#101 Symmetric Tree [Easy]

Key Insights

- Use recursion (or iteration) to compare pairs of nodes.
- For two trees (or two nodes) to be mirror images:
 - Their root values must be the same.
 - The left subtree of one must match the right subtree of the other.
 - The right subtree of one must match the left subtree of the other.
- Alternatively, iterative approaches using a queue can be applied to compare the nodes in pairs.

Space & Time

Time Complexity: $O(n)$, where n is the number of nodes in the trees, since we traverse each node once.
Space Complexity: $O(h)$ for recursive call stack (worst-case $O(n)$ for a skewed tree) or $O(n)$ for the iterative approach using a queue.

Solution

We solve the problem using recursion by defining a helper function that takes two nodes and checks if they are mirrors of each other. The helper function:

- Returns true if both nodes are null.
- Returns false if one node is null or if their values differ.
- Recursively compares the left child of the first node with the right child of the second node, and vice-versa. This method ensures each comparison verifies symmetry at every level. A similar logic can be applied iteratively by using a queue to compare pairs of nodes.

#104 Maximum Depth of Binary Tree [Easy]

Key Insights

- Use a recursive strategy (DFS) to traverse the binary tree.
- At each node, compute the maximum depth of its left and right subtree.
- The maximum depth at the current node is 1 (current node) plus the maximum of the left and right subtree depths.
- Alternatively, an iterative approach using BFS (level-order traversal) can be used.

Space & Time

Time Complexity: $O(n)$, where n is the number of nodes, since every node is visited once.
Space Complexity: $O(h)$ for recursion stack in DFS, where h is the height of the tree (worst-case $O(n)$ for a skewed tree); $O(n)$ for BFS in the worst-case scenario if the tree is balanced.

Solution

The problem is approached using Depth-First Search (DFS) with recursion. The idea is to visit every node and calculate the maximum depth of the left and right subtrees, then add 1 for the current node. This method naturally handles the base case when a null node (empty tree) is reached by returning 0. Alternatively, a Breadth-First Search (BFS) approach can determine the tree level by level, with the total number of levels equalling the maximum depth. Key data structures include recursion call stack for DFS or a queue for BFS.

#108 Convert Sorted Array to Binary Search Tree [Easy]

Key Insights

- The array is sorted in ascending order, which allows the use of a divide and conquer strategy.
- Choosing the middle element of the array as the root ensures that the left and right subtrees are roughly equal in size, yielding a balanced BST.
- A recursive approach is natural for building the tree: the base case is when the subarray is empty.
- The algorithm splits the array into two halves to recursively build the left and right subtrees.

Space & Time

Time Complexity: $O(n)$ - Every element is processed exactly once.
Space Complexity: $O(n)$ - $O(n)$ space is used to store the BST, and additional $O(n)$ space may be used for the recursion stack.

Solution

We use a divide and conquer approach with recursion. The main idea is to select the middle element of the current subarray as the root node so that the left subarray elements form the left subtree and the right subarray elements form the right subtree, ensuring the tree is balanced. The recursion continues until the subarray is empty, which serves as the base case. This strategy naturally maintains the BST property since all elements in the left subarray are smaller than the root, and all in the right subarray are larger.

#110 Balanced Binary Tree [Easy]

Key Insights

- Use a bottom-up DFS (Depth-First Search) traversal to compute the height of each subtree.
- If any subtree is found unbalanced, propagate an error indicator (e.g., -1) upward, allowing early termination.
- An empty tree is considered balanced.
- The key check is to ensure that for each node, the absolute difference between the heights of its left and right subtrees is no more than 1.

Space & Time

Time Complexity: $O(n)$ where n is the number of nodes in the tree, since we visit each node once.
Space Complexity: $O(h)$ where h is the height of the tree, which corresponds to the recursion stack ($O(n)$ in the worst-case of a skewed tree).

Solution

The solution uses a recursive DFS approach. A helper function recursively computes the height of a subtree. If a subtree is found to be unbalanced (the height difference between its left and right subtrees exceeds 1), the helper returns a special value (e.g., -1) to indicate that the subtree is unbalanced. This value is then propagated up the recursion to terminate further unnecessary computations. The main function checks the result of the helper function and returns true if the tree is balanced (i.e., the helper did not return -1) and false otherwise.

#112 Path Sum [Easy]

Key Insights

- Use a depth-first search (DFS) strategy to traverse the tree from the root to the leaves.
- At each node, subtract the node's value from the targetSum.
- Check if the node is a leaf; if yes and the remaining targetSum equals the node's value then a valid path is found.
- If the tree is empty, return false as no path exists.

Space & Time

Time Complexity: $O(N)$ where N is the number of nodes, since every node may need to be visited.
Space Complexity: $O(h)$ where h is the height of the tree, accounting for the recursion stack space in a skewed tree.

Solution

The approach uses a recursive depth-first search. The algorithm subtracts the current node's value from targetSum as it moves down the tree. When it reaches a leaf, it checks if the modified targetSum is equal to the leaf's value. If yes, it returns true. The recursion continues until either a valid path is found or all paths are exhausted. The primary data structure used here is the call stack for recursion.

#226 Invert Binary Tree [Easy]

Key Insights

- The problem can be solved using recursion (depth-first search) by swapping the children of every node.
- Alternatively, an iterative approach (using a queue for breadth-first search) can be used.
- The recursion terminates when a null node is encountered.
- The operation is performed in-place, modifying the original tree structure.

Space & Time

Time Complexity: $O(n)$ where n is the number of nodes, since each node is visited once.
Space Complexity: $O(h)$ where h is the height of the tree, which is the recursion stack space in a recursive approach. In worst-case (skewed tree), this could be $O(n)$.

Solution

We solve the problem using recursion (depth-first search). The approach is to:

- Check the base case: if the node is null, simply return null.
- Recursively invert the left subtree and the right subtree.
- Swap the left and right children of the current node.
- Return the current node after the swap.

The recursive approach elegantly handles all nodes and ensures the inversion process covers the complete tree.

#270 Closest Binary Search Tree Value [Easy]

Key Insights

- BST property allows us to traverse the tree efficiently by comparing the target with node values.
- We can iteratively traverse the tree, moving left if the target is smaller than the current node's value and moving right if greater.
- At each node, calculate the absolute difference between node's value and the target, and update the answer if the difference is smaller—or equal with a smaller candidate value.
- This approach minimizes the search area by leveraging the inherent ordering in BSTs.

Space & Time

Time Complexity: $O(h)$ on average, where h is the height of the tree ($O(\log n)$ for a balanced tree, and $O(n)$ in the worst-case scenario for a skewed tree).
Space Complexity: $O(1)$ for an iterative solution (or $O(h)$ if using recursion due to the call stack).

Solution

We solve the problem by performing an iterative traversal of the BST. Starting at the root, we maintain a variable to store the value closest to the target. For every node encountered, we:

- Compute the absolute difference between the node's value and the target.
- Update the stored closest value if the computed difference is less than the current smallest difference; if the difference is the same, choose the smaller node value.
- Depending on whether the target is less than or greater than the current node's value, move to the left or right child accordingly. This approach efficiently defines a search path that is consistent with the properties of a BST.

#501 Find Mode in Binary Search Tree [Easy]

Key Insights

- The BST in-order traversal yields a sorted order, which helps in counting consecutive duplicates.
- A two-pass in-order traversal can be used: one pass to determine the maximum frequency (maxCount) and a second pass to collect all values that match this frequency.
- The solution can be implemented without extra space (apart from recursion stack) by leveraging constant space counters and state variables.

Space & Time

Time Complexity: $O(n)$, where n is the number of nodes, because each node is processed twice (once in each traversal).
Space Complexity: $O(h)$ where h is the height of the tree due to the recursion stack. $O(1)$ extra space is used aside from this.

Solution

We perform an in-order traversal of the BST twice. The first traversal determines the maximum frequency of any value in the BST by comparing the current node's value with the previously visited node. Since the in-order traversal processes nodes in sorted order, duplicate values are consecutive, making the counting simple. After calculating maxCount, we reset our state and perform a second in-order traversal to collect all node values with frequency equal to maxCount. The key trick is to leverage the BST property (sorted in-order traversal) to count frequencies in one pass without using additional data structures like hash maps.

#543 Diameter of Binary Tree [Easy]

Key Insights

- Use depth-first search (DFS) to explore the tree.
- The diameter at a node is the sum of the depths of its left and right subtrees.
- Track the maximum diameter found during the DFS traversal.
- Recursively calculating the depth of subtrees provides an efficient solution.

Space & Time

Time Complexity: $O(n)$, where n is the number of nodes in the tree.

Space Complexity: $O(n)$, in the worst-case scenario due to the recursion stack (skewed tree).

Solution

The solution employs a DFS traversal of the binary tree. At every node in the tree, compute the depth of the left and right subtrees. The sum of these depths gives the potential diameter (longest path through that node). Update a global maximum diameter variable if this sum exceeds the current maximum. Finally, return the maximum diameter after completing the DFS.

#572 Subtree of Another Tree [Easy]

Key Insights

- Use Depth-First Search (DFS) to visit each node in the main tree.
- At each node, check if the subtree starting from that node is identical to subRoot.
- A helper function is used to compare the structure and node values of two trees.
- Consider recursion as the primary approach to traverse and compare trees.
- Early exit when a mismatch is found can optimize average-case performance.

Space & Time
Time Complexity: $O(m \cdot n)$ in the worst case, where m is the number of nodes in the main tree and n is the number of nodes in the subtree trees.
Space Complexity: $O(\max(\text{depth of main tree, depth of subtree}))$ due to recursive call stack.

Solution

We solve the problem by performing a DFS traversal on the main tree. For each visited node, a helper function checks whether the subtree starting at that node is identical to subtree by comparing node values and recursively checking both left and right subtrees. This method leverages recursion effectively and provides early termination if mismatches occur, allowing for efficient traversal and comparison.

#98 Validate Binary Search Tree [Medium]

Key Insights

- Every node must adhere to a range: all nodes in the left subtree should be less than the current node, and all nodes in the right subtree should be greater.
- A recursive depth-first search approach works well by passing down the valid range (lower and upper bounds) for each node.
- Using the limits (negative and positive infinity) simplifies handling edge cases at the tree root.
- An in-order traversal would alternatively yield a sorted order for node values, but updating ranges directly is more intuitive for recursive implementation.

Space & Time
Time Complexity: $O(N)$, where N is the number of nodes, as each node is visited once.
Space Complexity: $O(H)$, where H is the height of the tree, due to the recursion stack.

Solution

We use a recursive approach to validate the BST property. We maintain two variables, low and high, representing the valid range for the current node's value. For the left child, the valid range becomes (low, node.val) and for the right child, it becomes (node.val, high). By checking if each node's value falls within its respective range, we can ensure that the tree satisfies the BST properties.

#102 Binary Tree Level Order Traversal [Medium]

Key Insights

- Use Breadth-First Search (BFS) to traverse the tree.
- A queue data structure is ideal for maintaining the order of nodes at each level.
- For every level, process all nodes currently in the queue and add their children for the next level.

Space & Time
Time Complexity: $O(N)$, where N is the number of nodes, because each node is processed once.
Space Complexity: $O(N)$, which accounts for the space used by the queue in the worst-case scenario.

Solution
This solution leverages a BFS approach using a queue. The algorithm starts by enqueueing the root node. Then, it enters a loop that continues until the queue is empty. For each iteration—representing one level of the tree—it computes the number of nodes at that level (levelSize), processes these nodes by dequeuing them, and collects their values. Their non-null children are then enqueued. The list of values for each level is added to the final result list. Key data structures include the queue (for managing nodes) and a list (to store level values).

#103 Binary Tree Zigzag Level Order Traversal [Medium]

Key Insights

- Use a breadth-first search (BFS) approach to traverse the tree level by level.
- Alternate the direction of traversal on each level to achieve the zigzag pattern.
- A flag or counter can be used to determine the order of nodes for the current level.

Trees & BST - LeetCodeMastery - By Pattern — 3409 — LeetCodeMastery

In both approaches, appropriate data structures (a queue for BFS or recursion with a list for DFS) are used to store nodes and track the traversal state.

#230 Kth Smallest Element in a BST [Medium]

Key Insights

- An in-order traversal of a BST visits nodes in increasing order.
- Use a counter to keep track of the number of nodes visited.
- As soon as the counter reaches k , the current node's value is the k th smallest.
- For frequent modifications (insertions/deletions) and queries, consider augmenting the BST with subtree counts.

Space & Time
Time Complexity: $O(N)$ in the worst-case scenario (when $k = N$), but on average the traversal may stop early.
Space Complexity: $O(H)$ where H is the height of the tree ($O(N)$ in the worst-case for a skewed tree).

Solution
We perform an in-order traversal of the BST which visits nodes in ascending order. During the traversal, we maintain a counter (or decrement k) to check when we have encountered the k th smallest element. When the counter reaches 0 (or k becomes 0), we capture the current node's value as our answer and return it. This approach is both simple and efficient for the given constraints.

#235 Lowest Common Ancestor of a Binary Search Tree [Medium]

Key Insights

- Utilize the BST property: for any node, values in the left subtree are less and values in the right subtree are greater.
- If both p and q have values less than the current node, the LCA must lie in the left subtree.
- If both p and q have values greater than the current node, the LCA must lie in the right subtree.
- When one node value is less than and the other is greater than (or equal to) the current node, the current node is the lowest common ancestor.
- An iterative approach is efficient and uses constant extra space.

Space & Time
Time Complexity: $O(H)$, where H is the height of the tree ($O(\log n)$ for balanced trees and $O(n)$ in the worst-case skewed tree).
Space Complexity: $O(1)$ with an iterative approach ($O(n)$ if using recursion due to call stack).

Solution
The solution leverages the BST properties. Algorithm:
- Start at the root node. - While the current node exists: if both p and q have values less than the current node's value, move to the left child. if both p and q have values greater than the current node's value, move to the right child. Otherwise, the current node is the split point where p and q diverge, so it is the lowest common ancestor. - Return the current node.
This approach efficiently finds the LCA using a single traversal from the root.

#236 Lowest Common Ancestor of a Binary Tree [Medium]

Key Insights

- Use a depth-first search (DFS) traversal to explore the tree.
- When a node's value is either p or q , it could be the LCA.
- Recursively find p and q in the left and right subtrees.
- If both left and right recursive calls return a non-null value, then the current node is the LCA.
- If only one side returns a non-null value, propagate that value up the recursion.

Space & Time
Time Complexity: $O(N)$, where N is the number of nodes in the tree since each node is visited once.

Trees & BST - LeetCodeMastery - By Pattern — 3411 — LeetCodeMastery

- Pass the current node's value and the length of the current consecutive sequence in the recursive call.
- When a node's value is exactly one greater than its parent's value, increment the sequence length; otherwise, reset it to 1.
- Keep track of the maximum sequence length found during the traversal.

Space & Time
Time Complexity: $O(N)$, where N is the number of nodes in the tree, since each node is visited once.
Space Complexity: $O(H)$, where H is the height of the tree. In the worst-case of a skewed tree, the recursion stack can be $O(N)$.

Solution
The solution involves using DFS to explore every node in the binary tree while keeping track of the length of the consecutive sequence. For each node, if the node's value is one greater than its parent's value, we increment the sequence length; otherwise, we reset the sequence length to 1. During the traversal, a global variable is updated if the current sequence length exceeds the previously recorded maximum. This approach ensures that every possible consecutive path is considered.

#314 Binary Tree Vertical Order Traversal [Medium]

Key Insights

- Use Breadth-First Search (BFS) to traverse the tree level by level.
- Track the column index for each node where root is column 0, left child is column-1, and right child is column+1.
- Group nodes by their column indices using a hash table (or dictionary).
- BFS traversal naturally handles left-to-right ordering within the same level.
- Finally, sort the keys (column indices) to generate results from leftmost column to rightmost column.

Space & Time
Time Complexity: $O(n \log n)$ in the worst-case due to sorting the column indices in nodes in the worst-case if each node is on a unique column.
Space Complexity: $O(n)$ for storing the node information and the resultant structure.

Solution
The solution uses BFS with a queue that stores nodes along with their corresponding column index. For each visited node, add its value to a dictionary keyed by its column index. When processing children, update the column index appropriately (left child: col-1, right child: col+1). After the traversal, sort the keys of the dictionary and compile the node values in order from smallest to largest column index. This approach guarantees that nodes at the same level will be processed in left-to-right order, matching the required output.

#333 Largest BST Subtree [Medium]

Key Insights

- Use a bottom-up DFS (post-order traversal) to process each node.
- For each node, determine whether its left and right subtrees are BSTs.
- Maintain additional data per subtree: size (number of nodes), minimum value, and maximum value.
- A subtree rooted at the current node is a BST if:
 - Its left subtree is a BST.
 - Its right subtree is a BST.
 - The maximum value in the left subtree is less than the current node's value.
 - The current node's value is less than the minimum value in the right subtree.
- Track the size of the largest BST identified during the traversal.

Space & Time
Time Complexity: $O(n)$ (each node is visited once)
Space Complexity: $O(H)$, where H is the height of the tree (due to recursion stack)

Trees & BST - LeetCodeMastery - By Pattern — 3413 — LeetCodeMastery

- Using a double-ended data structure or simply reversing the list at every alternate level is an effective approach.
- Space & Time**
Time Complexity: $O(n)$, where n is the number of nodes, because each node is visited exactly once.
Space Complexity: $O(n)$, as in the worst-case scenario (e.g., a complete binary tree) the queue used for BFS may hold $O(n)$ nodes at once.

Solution

We can solve this problem using a breadth-first search (BFS). Start by initializing a queue to hold nodes for each level. For each level:
- Determine the number of nodes at the current level. - Iterate over these nodes, appending their children for the next level. - Depending on a flag (or level count), either append node values in the natural order (left to right) or reverse the order (right to left) before adding to the result. Key data structures:
- A queue for BFS traversal. - A list (or similar container) to store current level values. The main trick is toggling the order of insertion or reversing the list at alternate levels to achieve the "zigzag" pattern.

#105 Construct Binary Tree from Preorder and Inorder Traversal [Medium]

Key Insights

- Preorder traversal always starts with the root node.
- Inorder traversal splits the tree into left subtree and right subtree based on the root.
- A hash table (map/dictionary) can be used to quickly locate the index of the root in the inorder array.
- Use recursion to construct left and right subtrees.

Space & Time
Time Complexity: $O(n)$ since we process every node exactly once.
Space Complexity: $O(n)$ due to the recursion stack and the hash map used for inorder indices.

Solution

We solve the problem using a recursive divide-and-conquer approach. First, create a hash map to store each value's index in the inorder array for quick lookups. The preorder array always provides the current root. Use the inorder array to divide the tree into left and right subtrees. Recursively construct the subtrees by adjusting the preorder index and the boundaries of the inorder array. The algorithm leverages recursion and a hash map to achieve $O(n)$ time complexity.

#199 Binary Tree Right Side View [Medium]

Key Insights

- The problem is essentially about capturing the last node at each level for the rightmost node in a binary tree.
- A Breadth-First Search (BFS) approach naturally works by processing nodes level by level.
- Alternatively, Depth-First Search (DFS) can be adapted by prioritizing the right subtree first, ensuring that the first node encountered at each depth is the visible one.
- The number of nodes is capped at 100, so both approaches are efficient.

Space & Time
Time Complexity: $O(n)$ - visit every node in the tree.
Space Complexity: $O(n)$ - in the worst case, the queue (or call stack for DFS) may hold all nodes of the tree.

Solution

We can solve this problem using BFS (level-order traversal). The idea is to traverse the tree level by level using a queue. For each level, the last element added to the level represents the rightmost view from that level. We then append that element's value to our result list. Alternatively, a DFS approach can be used where we visit the right subtree first. By keeping track of the current depth and checking if it's the first time we've encountered this depth, we can add the first node visited at that depth (which will be the rightmost one) to the result.

Trees & BST - LeetCodeMastery - By Pattern — 3410 — LeetCodeMastery

Space Complexity: $O(H)$, where H is the height of the tree due to the recursion stack ($O(n)$ in the worst case of a skewed tree).

Solution

We solve the problem using recursion with depth-first search. The algorithm checks if the current node matches p or q . If then recursively searches the left and right subtrees. If both subtrees contain one of p or q , the current node is the LCA. Otherwise, the algorithm forwards the non-null result up the recursion. This approach naturally handles cases where one node is an ancestor of the other.

#250 Count Unvalue Subtrees [Medium]

Key Insights

- Perform a postorder traversal (left, right, root) to determine whether each subtree is unvalue.
- Treat null nodes as unvalue to ease the recursion.
- A node's subtree is unvalue if both left and right subtrees are unvalue and, if they exist, their values equal the current node's value.
- Use a global or external counter that increments every time a unvalue subtree is confirmed.

Space & Time
Time Complexity: $O(N)$, where N is the number of nodes, since each node is visited once.
Space Complexity: $O(H)$, where H is the height of the tree, due to the recursion stack.

Solution

We use a recursive DFS approach (postorder traversal) to solve the problem. For each node, we recursively check its left and right subtrees to decide if they are unvalue. By default, if a child is null, it is considered unvalue. Then, we verify the current node's value against its non-null children. If both conditions hold (subtrees are unvalue and matching values), we count the current node's subtree as unvalue. This DFS checks in a bottom-up manner, ensuring that the properties required for a subtree to be unvalue are maintained. The key trick is to return a boolean indicating if the subtree at each node is unvalue and, while backtracking, increment the counter appropriately.

#285 Inorder Successor in BST [Medium]

Key Insights

- In a BST, an in-order traversal yields nodes in ascending order.
- If the node p has a right subtree, the in-order successor is the left-most node in that right subtree.
- If p has no right subtree, the successor is one of its ancestors: traverse from the root towards p while keeping track of the last node that is greater than p .
- An iterative approach is efficient and avoids recursion stack overhead.

Space & Time
Time Complexity: $O(H)$, where H is the height of the tree. In the worst-case (skewed tree), it can be $O(n)$.
Space Complexity: $O(1)$ as only a constant amount of extra space is used.

Solution

We solve the problem using two cases:
- If node p has a right subtree, we simply find the left-most node in that right subtree. - If node p does not have a right subtree, initiate a search from the BST root. As we traverse: If the current node's value is greater than p val, the current node is a candidate for the successor; move to the left subtree to look for a smaller candidate. Otherwise, move to the right subtree. By the end of the traversal, the candidate (if exists) is the in-order successor. This approach benefits from the BST property, limiting traversal to $O(H)$ time.

#298 Binary Tree Longest Consecutive Sequence [Medium]

Key Insights

- Use a Depth-First Search (DFS) to traverse the binary tree.

Trees & BST - LeetCodeMastery - By Pattern — 3412 — LeetCodeMastery

Solution
Perform a post-order traversal of the binary tree. For each node, return a tuple (or object in some languages) that provides:
- Whether the subtree rooted at this node is a BST. - The size of the subtree if it is a BST (or the size of the largest BST found within it). - The minimum value in the subtree. - The maximum value in the subtree.
At each node, if both left and right children form valid BSTs and the current node's value fits the BST condition (greater than left's max and less than right's min), then the subtree rooted at the node is also a BST. Calculate its size and update the current global maximum if necessary. If the condition fails, return the maximum BST size found in its subtrees.

#366 Find Leaves of Binary Tree [Medium]

Key Insights

- Use a postorder traversal (bottom-up approach) to process the tree.
- Determine the "height" of each node (distance from the deepest leaf) where leaves have a height of 1.
- Group nodes by their computed height to simulate the layer-wise removal of leaves.
- The same node may become a leaf after its children are removed.

Space & Time
Time Complexity: $O(n)$ - Each node is visited exactly once.
Space Complexity: $O(n)$ - Space used for the recursion stack and the result list.

Solution

The solution uses a recursive helper function that performs a postorder traversal of the tree. For each node, it computes its height as $\max(\text{height of left, height of right}) + 1$. Nodes with the same height are collected together in a list. This idea mirrors the process of removing leaves level by level, where leaves (height 1) are removed first, then their parents become new leaves, and so on. Data Structures used:
- An array or list to maintain the groups of node values by their height. Algorithmic Approach: - Use Depth-First Search (DFS) via recursion. - Postorder traversal ensures that leaf nodes (base cases) are processed before their parents. - Append the node's value to the correct list based on the computed height.

#437 Path Sum III [Medium]

Key Insights

- A path can start and end at any nodes, as long as it goes downwards.
- Using DFS helps traverse the tree and explore all possible paths.
- A prefix sum technique with a hash map allows quick calculation of the sum of any subpath.
- Backtracking is used to remove a path's prefix sum when moving back up the recursion tree.
- Although a brute-force approach exists, it is inefficient compared to the prefix sum method.

Space & Time
Time Complexity: $O(n)$ on average (where n is the number of nodes), though worst-case can be $O(n^2)$ in a skewed tree.
Space Complexity: $O(n)$ due to recursion stack and the hash map that stores prefix sums.

Solution

The solution employs a DFS traversal of the tree along with a hash map that records the frequency of prefix sums encountered so far. At each node, the current prefix sum is updated by adding the node's value. We then check the hash map for how many times each current prefix sum - targetSum has occurred, since this value indicates the existence of a subpath summing to targetSum. We update the hash map with the current prefix sum, continue the DFS to traverse child nodes, and then backtrack by decrementing the current prefix sum's count before returning to the parent node. This ensures that sums from other branches are not incorrectly combined.

#545 Boundary of Binary Tree [Medium]

Trees & BST - LeetCodeMastery - By Pattern — 3414 — LeetCodeMastery

Key Insights

• Break down the problem into three parts:

- Left boundary (excluding leaves).
- All leaves (do a DFS to find leaves).
- Right boundary (excluding leaves, then reverse the collected list).
- Special handling is needed when the tree doesn't have a left or right subtree.
- The root is always included and is never considered as a leaf, even if it has no children.
- Avoid duplication of leaf nodes in the left/right boundaries.

Space & Time

Time Complexity: O(n) - Every node is visited at most once.

Space Complexity: O(n) - O(n) space is used for the output list and recursion stack (in worst case tree is skewed).

Solution

The solution uses a Depth-First Search (DFS) strategy to traverse the tree and collect the boundary nodes in three steps:

- For the left boundary, start at root.left and traverse down, adding nodes (skipping leaves).
- For the leaves, perform a DFS from the root and add any node that has no children.
- For the right boundary, start at root.right and traverse down, adding nodes (skipping leaves).
- Since the right boundary must be added in reverse order, we reverse the collected list after traversal.
- Finally, concatenate these lists in the order: root, left boundary, leaves, reversed right boundary.

The approach makes use of helper functions to clearly separate the logic for gathering left boundary, leaves, and right boundary. This modular approach simplifies reasoning and avoids edge case mistakes such as including duplicate leaf nodes.

#549 Binary Tree Longest Consecutive Sequence II [Medium]

Key Insights

• Use Depth-First Search (DFS) to visit every node.

- For each node, compute:
- The longest increasing consecutive path starting from that node.
- The longest decreasing consecutive path starting from that node.
- Combine the increasing and decreasing paths (subtracting one to avoid double counting the current node) to potentially form a longer consecutive sequence through the node.
- Update a global maximum to record the longest path seen.

Space & Time

Time Complexity: O(n), where n is the number of nodes since every node is visited once.

Space Complexity: O(h), where h is the height of the tree, due to the recursion stack.

Solution

The solution employs a DFS traversal. At every node, we calculate two values:

- inc - the length of the longest increasing consecutive sequence starting from that node.
- dec - the length of the longest decreasing consecutive sequence starting from that node.

For each child of the current node:

- If the child's value is node.val + 1, update the increasing sequence.
- If the child's value is node.val - 1, update the decreasing sequence.

Then, the longest path through the current node is inc + dec - 1 (subtracting one to avoid counting the current node twice). A global variable maintains the maximum length encountered. This process works regardless of the path direction because it combines both increasing and decreasing parts.

#582 Kill Process [Medium]

Trees & BST - LeetCode - By Pattern

— 3415 —

LeetCode

- Build an undirected graph representation of the binary tree using a DFS. For each node, add the node's value as a key in an adjacency list and connect it with its children (if any). This creates bidirectional links between parent and child.

- Use a BFS starting from the target node and explore nodes level-by-level. Keep a counter for the current distance, and once the counter reaches k, return all node values found at that level. To avoid processing nodes more than once, maintain a set of visited nodes.

#1120 Maximum Average Subtree [Medium]

Key Insights

- Use a depth-first search (DFS) to traverse every subtree.
- At each node, compute the sum and count of nodes in its subtree.
- Calculate the average for the current subtree and update a global maximum if needed.
- Processing every node exactly once yields an efficient solution.

Space & Time

Time Complexity: O(n), where n is the number of nodes (each node is visited once).

Space Complexity: O(h), where h is the height of the tree (space for recursion stack).

Solution

We perform a post-order DFS traversal, calculating at each node both the cumulative sum and the count of nodes in its subtree. This enables us to compute the average value in constant time for any subtree. We maintain a global variable to track the maximum average encountered during the traversal. The primary technique is recursive DFS combined with tuple (or pair) aggregation. The simplicity of the recursion and in-place aggregation ensures an efficient and clear solution.

#1490 Clone N-ary Tree [Medium]

Key Insights

- The tree is N-ary, meaning every node can have multiple children.
- A deep copy requires creating new nodes for each node in the tree.
- Both DFS (recursive) or BFS (iterative) traversals can be used to clone the tree.
- The overall time complexity is O(N) since each node is visited once.
- We can follow similar cloning techniques used in cloning graphs, using either recursion or an auxiliary data structure like a queue.

Space & Time

Time Complexity: O(N), where N is the number of nodes in the tree, since each node is visited exactly once.

Space Complexity: O(N), accounting for the recursive call stack (or an explicit queue in BFS) and the space needed to store the clone.

Solution

We perform a DFS traversal starting from the root node. For each node we encounter, we:

- Create a new node with the same value.
- Recursively clone all its children and attach the cloned children to the new node.

This approach ensures that every original node is copied into a new node and that the parent-child relationships are preserved. Edge cases such as an empty tree (null root) are also handled by returning null immediately.

#1522 Diameter of N-Ary Tree [Medium]

Key Insights

- The diameter of the tree can be found by considering the two largest depths from any node among its children.
- Use a depth-first search (DFS) to compute the maximum depth from each node.
- For each node, the potential diameter is the sum of the two longest depths among its children.
- Update a global variable tracking the maximum diameter as you recurse through the tree.

Space & Time

Time Complexity: O(n) for both serialization and deserialization, where n is the number of nodes in the tree.

Space Complexity: O(n) due to the storage used for the serialized string and additional data structures (queue) during processing.

Solution

This solution uses level-order traversal (BFS) for both serialization and deserialization. During serialization, each node is processed sequentially with missing children recorded as "null". For deserialization, the string is split by commas, and a queue is used to rebuild the tree level by level. The root is created from the first token, then subsequent tokens are assigned as left and right children accordingly, ensuring an accurate reconstruction of the original tree.

Key Insights

- The tree can be traversed using either depth-first search (DFS) or breadth-first search (BFS).
- Using BFS (level-order traversal) simplifies reconstruction since nodes are processed level-by-level.
- Placeholder markers (e.g., "null") are used to indicate missing children.
- Both serialization and deserialization processes should handle empty trees and edge cases gracefully.
- Ensuring a one-to-one mapping between the tree structure and the serialized string is critical.

Space & Time

Time Complexity: O(n) for both serialization and deserialization, where n is the number of nodes in the tree.

Space Complexity: O(n) due to the storage used for the serialized string and additional data structures (queue) during processing.

Solution

This solution uses level-order traversal (BFS) for both serialization and deserialization. During serialization, each node is processed sequentially with missing children recorded as "null". For deserialization, the string is split by commas, and a queue is used to rebuild the tree level by level. The root is created from the first token, then subsequent tokens are assigned as left and right children accordingly, ensuring an accurate reconstruction of the original tree.

Trees & BST - LeetCode - By Pattern

— 3419 —

LeetCode

Key Insights

- Build a mapping (dictionary/hash table) from a parent process ID to its list of child process IDs.
- Use Depth-First Search (DFS) or Breadth-First Search (BFS) starting from the kill process to traverse the tree and collect all descendant processes.
- The problem requires handling a tree structure that may have multiple children per node.

Space & Time

Time Complexity: O(n), where n is the number of processes (both building the mapping and the tree traversal take linear time).

Space Complexity: O(n), for storing the mapping and the traversal queue/stack.

Solution

We first construct a mapping from each process's parent ID to its list of child IDs. This allows us to quickly access all children of any process. Once the mapping is built, we perform a tree traversal (either BFS or DFS) starting from the process to kill. During the traversal, we record every process encountered. This collected list represents all processes that will be terminated. The data structures used are a dictionary (for the mapping) and either a stack (for DFS) or a queue (for BFS), making the solution efficient and straightforward.

#662 Maximum Width of Binary Tree [Medium]

Key Insights

- Perform a level order traversal (BFS) of the tree.
- Assign an index to each node as if the tree were complete (e.g., root is index 1, left child is 2
- 1 , right child is 2
- $i+1$).
- For each level, compute the width as (last_index - first_index + 1).
- Using indices allows capturing gaps between nodes due to nulls in between.
- Edge cases include handling very skewed trees.

Space & Time

Time Complexity: O(N), where N is the number of nodes in the tree.

Space Complexity: O(N), due to the queue used for BFS which in the worst case holds nodes of the last level.

Solution

We use a Breadth-First Search (BFS) approach with a queue to traverse the tree level by level. At each level, we pair each node with an index representing its position assuming a complete binary tree. This allows us to compute the width of each level using the formula: width = last_index - first_index + 1. We then track the maximum width seen throughout the traversal. The use of indices handles cases where there are null gaps between nodes.

#863 All Nodes Distance K in Binary Tree [Medium]

Key Insights

- Convert the binary tree into an undirected graph so that we can easily traverse both down to the children and up to the parent.
- Use a DFS or simple recursive traversal to create an adjacency list representing the graph.
- Perform a BFS starting from the target node to explore nodes level-by-level until reaching distance k.
- Use a visited set (or equivalent) to avoid revisiting nodes and to prevent cycles.

Space & Time

Time Complexity: O(N), where N is the number of nodes in the tree. Each node is visited once when constructing the graph and once in the BFS.

Space Complexity: O(N), for storing the graph and the additional data structures used in BFS and DFS.

Solution

The solution involves two main steps:

Trees & BST - LeetCode - By Pattern

— 3418 —

LeetCode

Time Complexity: O(n), where n is the number of nodes, since each node is visited once.

Space Complexity: O(h), where h is the height of the tree, due to the recursion stack (worst-case O(n) for a skewed tree).

Solution

Use a DFS approach to traverse the tree. At each node, calculate the longest and second longest depth among its children. The sum of these two depths gives the candidate diameter through that node. Maintain a global variable to track the maximum diameter found so far. Return the maximum depth from the node i.e., one plus the largest depth among its children) to be used in parent's calculations.

#1650 Lowest Common Ancestor of a Binary Tree III [Medium]

Key Insights

- Each node has a parent pointer, so you can traverse from any node to the root.
- By determining the depth of each node, you can "align" the two nodes to the same depth.
- When both nodes are aligned, traverse upward simultaneously until they meet.
- This approach guarantees finding the LCA with O(h) time complexity, where h is the height of the tree.

Space & Time

Time Complexity: O(h), where h is the height of the tree.

Space Complexity: O(1)

Solution

We first compute the depth of both nodes by moving up their parent pointers. If one node is deeper, move it upward until both nodes are at the same level. Then, move both nodes upward one step at a time until they meet; the meeting point is the lowest common ancestor. This approach uses constant extra space and leverages the parent pointer for an efficient solution.

#124 Binary Tree Maximum Path Sum [Hard]

Key Insights

- Use Depth-First Search (DFS) to explore the tree in a post-order fashion.
- For each node, calculate the maximum gain including that node and optionally one of its subtrees.
- A node's best contribution to its parent can be either just its own value or its value plus the maximum gain from either the left or right child.
- Update a global maximum path sum that considers the possibility of combining both left and right gains with the current node.
- Handle negative values by comparing gains against 0 to avoid decreasing the path sum.

Space & Time

Time Complexity: O(n), where n is the number of nodes in the tree, since each node is visited exactly once.

Space Complexity: O(n) in the worst-case scenario due to the recursion stack (O(h) where h is the height of the tree, which can be O(n) for skewed trees).

Solution

We use a recursive DFS approach (post-order traversal) to compute the maximum gain from each subtree. For every node:

- Recursively compute the maximum gain from the left and right child, ensuring that negative gains are treated as 0.
- The maximum gain that can be provided to the node's parent is the node's value plus the larger gain from its left or right child.
- Simultaneously, the potential maximum path sum including the current node as the highest (or root) node is the node's value plus both left and right gains.
- Update a global variable that holds the maximum path sum found so far.
- Return the maximum gain (node value plus one best child to be used by the node's parent).

This strategy ensures that every possible path sum is considered while avoiding double-counting nodes.

#297 Serialize and Deserialize Binary Tree [Hard]

Trees & BST - LeetCode - By Pattern

— 3418 —

LeetCode
